Dr. A. Brothers, of this city, reports the following: "On April 16th the family of Mr. S—— had supper at 7 P.M. The meal consisted principally of eggs which had been boiled that morning and allowed to remain all day in the warm kitchen. Although it was noticed at the time that the eggs had a bad odor, still they were eaten by the father and four of the children, ranging between two and twelve years of age. The mother and the remaining two boys did not partake of them. Within an hour every one of the five who had eaten the eggs became sick. I was sent for at 11 P.M. and found them suffering from symptoms evidently due to acute irritant poisoning. Prostration was very marked. Retching was present, and there was frequent vomiting. The matter vomited consisted of bad-smelling food and mucus, strongly tinged in one case with blood. Cramps referred to the stomach caused several of the children to cry out from time to time with pain. Thirst was extreme, but the water taken to quench it at once excited vomiting. Diarrhœa, with yellow watery movements having a strong odor of rotten eggs, was present in all the cases. Stupor, with a desire to be left alone, was also a prominent symptom. After awhile the father and two of the children passed into a condition of collapse, and it looked as if they might die at any moment. They lay with the eyes half closed, showing the whites of the eyeballs. The pupils in some were contracted, in others dilated. The extremities were cold and the skin was covered with a clammy sweat. The pulse in the father was about 70, but extremely soft and compressible, and at one time almost imperceptible. In the children the pulse ranged between 120 and 180. The temperature in most of the cases was subnormal. After several hours, improvement set in, and next day they were all out of danger. In the treatment of the cases I was assisted by Dr. J. Horn. After emptying the stomach by the use of sulphate of zinc and washing out the stomach in one of the older children, calomel in mucilage was given to clean out the intestinal tract. For the vomiting occurring after this and also to quench the burning thirst, ice proved to be of great service. When the cases passed into a condition of collapse, heat was applied to the extremities, tablets of digitalin were given by the mouth, and brandy was administered hypodermatically."

GONORRHŒA AND STRICTURE.

Dr. W. S. Richardson, of Marlborough, Mass., writes: "Does stricture cause irritation, or irritation cause stricture? The talk is all about stricture causing irritation. It increases irritation no doubt. The idea seems to be that if the stricture is removed the irritation will go away. It is a common thing for a sensitive urethra to contract so that a catheter cannot be passed till the urethra becomes habituated to its presence. The constant irritation of a gonorrhœal inflammation the urethra *never* gets accustomed to till the inflammation begins to subside. In every case of gonorrhœa the inflammation is a constant stimulus to contraction. When the irritation is removed, if it is removed soon enough, there is no more contraction. If, for any reason, the inflammation stays for any length of time, from two to six months, there is that constant tendency to contraction—the urethra trying to eject the cause of irritation. It is likely that this continued effort will be followed by the proliferation of the elements of the submucous tissue at certain parts of the canal. This idea suggests a treatment for gonorrhœa or gleet with stricture. In the treatment of a chancroid we seek to produce a healthy unhealed surface by using one or two strong applications, and then heal this surface by continued mild applications. With hard resisting strictures there is no doubt an organic change, but if a medium-sized instrument can be passed and applications made and the irritation removed, the stubbornness of the organic (?) stricture will not be troublesome. Has success in a few cases made one observer an enthusiast over a *false* notion; or is there some sense in the above theory? There has been some trouble somewhere or there would not be so much talk about the difficulty of curing gonorrhœa and stricture."

MARGINAL PLACENTA PRÆVIA.

Dr. J. M. Baldy, of Philadelphia, writes that the report of Dr. Brown's case in a recent issue of The Medical Record calls to his mind a similar case occurring in his own practice. "Mrs. W——, colored, aged thirty-two; married eleven years; has had seven children. She had expected to be confined in about two months, but thought she might possibly be sooner, as she had been bleeding freely at times for the past few weeks. I explained to her the probability of there being a complication, and she went home with the understanding that I was to be sent for immediately if she began to have pains or began to bleed again. There was at this time no dilatation of the cervix.

"Two weeks later a messenger summoned me to my patient at mid day. I found the anterior vaginal wall protruding from the vagina in a mass as large as a base-ball. This being reduced, the cervix was found well dilated. The pains were very weak and far apart. The lower margin of the placenta could easily be felt attached low down to the left and partially presenting. The finger could be freely swept around the os in other directions and readily introduced into the uterus. The presenting part was high up, and was found to be the breech The patient told me that she had been losing blood continually since she last saw me, and her appearance

testified to the truthfulness of her statement. She had, however, been losing very little blood that day, and was feeling better. I was forced to leave her for a short while, expecting to return in half an hour, rupture the membranes, and deliver rapidly. I was detained almost an hour, and on my return I found the labor over, with the child and placenta between the patient's thighs. All bleeding had ceased, and the uterus was well contracted. On inquiry I found that about half an hour after I had gone she 'suddenly felt something turn inside her,' and this feeling was followed by several very strong pains, which ended the labor. The woman in attendance informed me that the head was delivered first, and the placenta followed immediately after the breech, together with a free gush of blood. It was an eight-months' child, small and emaciated. The baby died the second day, but the mother did well and slowly regained her lost strength.

"The possibility of a mistake in the diagnosis of the presentation in this case has often occurred to me; but as I had made my examination most thoroughly and carefully, and as the patient was such an excellent subject for examination, the probability of such a mistake is very slight, and I have finally dismissed it altogether. I think that cases of marginal placenta prævia are often safely ended without any interference on the part of the attending physician. I know of a number of such among my friends. The proper treatment is, however, to deliver the child as quickly as possible, and run no unnecessary risks from hemorrhage."

CICATRICIAL ADHESIONS FOLLOWING A BURN.

Dr. W. P. Copeland, of Eufaula, Ala., reports the following case: "The patient was a negro, about twenty years of age. When a boy, he was burned from the left shoulder down the back, left arm, and side. He was not attended by a physician at the time, and from ignorance his parents allowed the arm to adhere to the side, to which it was firmly bound down from the elbow to the axilla in a continuous cicatricial band on both anterior and posterior aspects of arm. He was presented for operation eleven years after receiving the burn. The patient was chloroformed, and the arm was dissected from the side, leaving a broad uncovered surface on the inner aspect of arm and down left side. It was with the greatest difficulty that the arm could be moved away from the side, owing to its long confinement in one position. After stitching the skin together, a layer of dry navy-lint was applied. The wound on the arm healed readily, but the one on side, owing to the contractility of the cicatricial tissue, did not heal by first intention. The dressings were left off, and a loose garment was worn, with a towel around the waist to catch and absorb the secretions, which were soaked up once or twice a day with dry absorbent cotton. Neither water nor any medicated washes were used. The wound healed rapidly and well, and the man now has full and complete use of his arm."

A CASE OF PHTHISIS PULMONALIS TREATED BY BERGEON'S METHOD.

Dr. A. R. Jenkins, of Henderson, Ky., reports the following: "About three weeks since, in consultation on a case of confirmed phthisis, it was suggested to make trial of Bergeon's treatment. The patient, a fourteen-year old girl, was in the last stages of the malady—cough, indigestion, with continuous gastric and intestinal colic, were the most distressing symptoms. The injections were given twice daily for the first few days, without at first any improvement being manifest. Then the quantity of sulphuretted water and gas was increased considerably, after which the patient took food less fearfully, and there was an apparent improvement."

Progress of Medical Science.

On Chronic Poisoning by Tobacco.—At a recent meeting of the Royal Imperial Society of Physicians of Vienna, Favarger made a communication on the above old, but ever new subject, of which the subjoined is a *résumé*. The symptoms of chronic nicotism do not generally manifest themselves till after the usage of strong tobacco for ten years or more, and ordinarily follow the free smoking of Havana cigars. As for the manner of smoking, there are four types of smokers: (1) Those who swallow the smoke; in these cases the nicotine acts, probably, directly on the stomach; (2) those who only breathe in and breathe out the smoke: here the detrimental action remains limited to the pharynx and the larynx; (3) some smokers keep their cigar constantly between their lips, and are in the habit of swallowing a certain quantity of nicotine mingled with their saliva; (4) there are other smokers who use cigar-holders that are soon fouled with nicotine, and are never properly cleaned. Chronic poisoning by nicotine manifests itself generally by disturbances of the circulation and digestion. One of the most frequent symptoms is palpitation, then next in the order of frequency is cardiac asthma, and still more rarely occur attacks of angina pectoris. Physical examination of the heart gives sometimes negative results, and sometimes reveals the existence of chronic myocarditis, or of fatty degeneration of the heart. Among the digestive derangements are noted: loss of appetite, pain in the epigastric region, diarrhœa, or constipation. Among the symptoms pointing to disorder of the nervous system are insomnia and attacks of syncope. Favarger reported a remarkable case of fatty degeneration of the heart in a man, aged sixty, who had been for many years an inveterate smoker of strong Havanas. Several weeks before his death he was attacked, after a meal, with violent palpitation, and a paroxysm of dyspnœa came on the next day. Till the time of his death the temperature remained low (94°–97° F.), the pulse very frequent and small (140 to 160), and the pupils much contracted. At the autopsy were found pleuritic exudations, dilatation, with fatty degeneration of the heart, and an ulcer of the stomach, which had determined a mortal hemorrhage. In this case, said the reporter, the fatty degeneration of the heart could not be attributed to alcoholism, or any other known cause, except that which was the most obvious, namely, the excessive use of tobacco. This view was confirmed by the abnormal frequency of the pulse, by the great fall in the bodily temperature, and by the contraction of the pupils. Although no arterial atheroma was noted, there existed, nevertheless, in this case a functional stenosis (?) of the coronary arteries, equally attributable to nicotine, and to this constriction of the nutrient arteries of the heart, causing ischæmia, was due, presumably, the fatty degeneration of that organ. As for the ulcer of the stomach, it may have been directly engendered by the topical action of saliva impregnated with nicotine, or it may have been the result of circulatory disturbances, according to the process indicated by Rokitansky and Virchow. As for the treatment of chronic nicotism, Favarger recommends as prophylactic means: (1) Never to smoke when the stomach is empty, but always after a meal. In this way the number of cigars smoked will be limited, the nicotine will be made to act on a full stomach, loss of appetite will be prevented, and the antidotal ("anti-nicotine") action of the tannin contained in the wine, tea, or coffee of the meal will be obtained. Tannin, according to Favarger, is the best antidote to nicotine. (2) Smokers should avoid holding their cigars long in their mouths. (3) Cigar-holders should be frequently renewed, and regularly cleaned. Smokers should smoke the milder cigars occasionally, instead of always choosing the strongest. According to Erlenmeyer (Stillé, "Therapeutics," vol. II., p. 320) smoking

cigars is vastly more injurious than smoking a pipe, because the preparation of tobacco for the latter purpose destroys as much as two-thirds of its nicotia, while the former loses but little of its active principle in the manufacture. More than twenty-five years ago, Dr. B. W. Richardson presented the following conclusions as the result of an exhaustive study of the effects of tobacco-smoking: (1) The effects produced are very transitory. (2) The evils of smoking are functional in their character, and statements that it causes insanity, epilepsy, chorea, apoplexy, organic disease of the heart, cancer, and consumption are devoid of fact. (3) The habit of smoking is deleterious to the young. (4) Tobacco is a luxury, but probably the least hurtful of the luxuries. Stillé, in commenting on these propositions, remarks that there are several diseases not enumerated by Dr. Richardson which excessive smoking unquestionably develops. One of these is amaurosis, many cases of which have been traced to tobacco-smoking by no less competent authorities than Mackenzie and Sichel. "The former, many years ago, hinted his suspicion that it is a frequent cause of amaurosis, and the latter is now of opinion that there are few persons who have smoked during a long period more than five drachms of tobacco per diem, without having their vision, and frequently their memory impaired." Farnsworth, in the *American Medical Times* (October, 1862), cites a case of impaired vision from the same cause, with general anæsthesia. "In spite of a well-directed treatment the disease grew worse, until the discovery was made that the patient was in the habit of smoking a pipe almost continually, with the coarsest kind of tobacco. On relinquishing this practice he gradually recovered."—*The Boston Medical and Surgical Journal.*

The Distribution of Phthisis.—The third volume of Hirsch's great work, "A Handbook of Geographical and Historical Pathology," recently issued by the New Sydenham Society, contains, among much valuable information, some striking, and to many, no doubt, novel facts regarding the incidence of pulmonary phthisis. It is, as Professor Hirsch remarks, emphatically a disease of all times, all countries, and all races. No climate, no latitude, no occupation, no combination of favoring circumstances forms an infallible safeguard against the onset of tuberculosis, however such conditions may mitigate its ravages or retard its progress. Like typhoid fever, phthisis dogs the steps of man, wherever he may be found, and claims its victims among every age, class, and race. A summary of results shows that the average number of deaths from phthisis is about 3 per 1,000, or nearly one-seventh of the total mortality. The first fact which comes out clearly from Professor Hirsch's tabulated data is the relatively large mortality from phthisis in the large centres of population. Thus Vienna has a death-rate from this cause of 7.7 per 1,000, or more than twice the general average. Pesth is credited with 6.9 per 1,000, Brussels with 5.6, Stockholm with 4.1, Munich and Glasgow with 4, Berlin and Dresden with 3.8. In the smaller towns the rate sinks to 3 or 2.5 per 1,000, and in rural districts the mortality is still less. Many facts are at hand to show that an increased liability to phthisis goes, *pari passu*, with rapid growth of population, and especially with the massing together of large bodies of workers engaged in arts and manufactures. Impure air and hygiene are undoubtedly the most potent factors in the genesis of the disease, and take precedence even of hereditary predisposition and imperfect nutrition. Among nomad tribes, such as the Kirghiz of the Central Asian steppes, or the Bedouins of Arabia, the disease is practically unknown; but there is much instruction and warning for us in the fact that when, as sometimes happens, these wandering tribes settle in the towns their immunity immediately ceases. The influence of geographical position upon phthisis turns out to be much less than current opinion would indicate. We are prone to regard it as essentially a malady of temperate latitudes, and of the Anglo-Saxon race, but more accurate statistical information proves that it is very virulent in many warm countries, and that some of the inferior races, such as the negroes, the inhabitants of the West India Islands, and the peoples of the South Sea suffer more in proportion than the nations of Europe. It will be a great surprise to many people to learn that the death-rate from phthisis is as high in sunny Italy as in foggy England. Those who hold the old-fashioned notion that damp and cold are the main causes of phthisis will be puzzled to account for the almost complete immunity enjoyed by the inhabitants of the Hebrides and the Faroe Islands. Latitude is not, however, without a distinct influence, but upon the prevalence and the type of phthisis. The disease becomes rarer as we approach the poles, and is extremely infrequent within the limits of the Arctic and Antarctic Circles. In the Tropics the disease does not conform to the ordinary chronic form familiar to medical observers in this country, but in the brevity and severity of its course approximates rather to acute tuberculosis. While the influence of latitude is comparatively slight, irregular, and apt to be counteracted by other conditions, that of altitude is most potent. Among the higher Alps, the Andes, the elevated plateaux of Mexico, Persia, and South Africa, we approximate, though probably never quite attain to, conditions of absolute immunity. In India the disease is tolerably common, and very pernicious on the lowlands, while it is extremely rare upon the upper slopes of the Himalayas, the Ghauts, and the Neilgherries. At Bogota and Quito, in spite of the aggregation of large populations, the disease is excessively rare, and is practically limited to settlers from the lowlands or from other countries. Even at Potosi, among a population engaged in mining, and amid conditions of very imperfect hygiene, phthisis can scarcely gain a footing. It is thus evident that the protective influence of high altitude suffices to counteract other forces which usually occasion a widespread prevalence of the disease. The extremely low mortality from phthisis in Switzerland, namely, 1.86 per 1,000, is explained by the fact that so large a proportion of the people reside at a considerable altitude above the sea-level, although the sparseness of the population, no doubt, also operates in the same direction. The influence of a damp soil in promoting phthisis is now well established, and suggests obvious practical conclusions. The incidence of phthisis in the Australasian colonies is of much interest, in view of their popularity as refuges for the consumptive. The large towns of Australia have now a death-rate from phthisis of over 2 per 1,000, and present little advantage to the phthisical sufferer over his own country. On the other hand, the large inland plains of Australia are almost exempt from phthisis, and constitute a genuine sanatorium. In New Zealand phthisis has made frightful ravages among the Maoris, and is the chief factor in their approaching extinction; but the explanation of this fact is not to be sought in any adverse climatic influence, but rather in the miserable dwellings and wretched food of the native inhabitants of these islands. Professor Hirsch's conclusions may be thus briefly summed up: Phthisis is everywhere prevalent, but it is rare in polar regions, and rarer still at high altitudes. The main factor in its production is overcrowding and bad hygiene. Heat and cold, *per se*, have no influence. Damp, when conjoined with frequent oscillations of temperature, predisposes to the disease; but humidity of the air is less important than dampness of soil. Occupation is extremely important, but mainly indirectly, as tending to good or bad hygienic conditions.—*The British Medical Journal.*

Professor Virchow's address on myxœdema has called attention to this disease in Germany, and now another case is reported by Dr. L. Landau in the *Berlin. Klin. Woch.*, No. 2. This makes the fifth reported from Germany; Reiss, Erb, and Senator having reported the previous four in the same periodical (1886, No. 5; 1887, No. 1; 1887 No. 9).

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 14, 1887.

A NEW METHOD OF PREVENTING HEMORRHAGE AND TREATING ANEURISMS.

UNDER the above head Dr. C. S. Muscroft, of Cincinnati, describes his experience in the use of acupuncture previous to amputations as a substitute for digital compression, the tourniquet, and Esmarch bandage. He was led to an enthusiastic belief in the wide-reaching importance of this method by a successful application of it in a case of amputation at the hip-joint and in one of amputation at the shoulder. In the former case the method of employing the compression is described as follows:

As soon as the patient was fully under the influence of the anæsthetic, a needle, one-eighth of an inch wide, slightly bent at the point, about the thickness of a dime, and four inches long, was introduced perpendicularly into the front of the thigh, about an inch and a half below Poupart's ligament. The exact point of entrance was one-fourth of an inch internal to the combined sheaths of the vein, artery, and nerve. The point was pushed beyond the vessels, then turned outward until the needle had passed beyond them; the point was then pushed out through the integument. The needle was then behind the vessels and nerve. A piece of cord was passed under the heel and point of the needle, forming a figure-of-eight ligature. Before the ligature was applied the femoral artery could be felt pulsating strongly, but when it was tightened the pulsation below the needle had ceased entirely.

After the incisions had been made the femoral artery was found to be perfectly compressed.

Dr. Muscroft also claims that this method will be found useful in the treatment of aneurism in any part of the lower or upper extremities. He has found that the steel pin can be retained, without causing irritation, for four days. Then, if necessary, it can be removed and another introduced lower down.

While admitting that acupressure was an old surgical procedure, Dr. Muscroft claims that its application in the prophylaxis of hemorrhage, and in the surgical treatment of aneurisms, is new. The points made were summarized as follows:

1. The simplicity and easy applicability of the method.

2. There is no interference with the general venous circulation in nearly all cases.

3. The plan is so simple that it does away with all of the more complicated forms of compression of vessels by tourniquets, bandages, or tubing.

4. It is also a process for shutting off the arterial flow in cases of aneurisms.

5. The introduction of the pin or needle will, in most cases, be an entirely bloodless operation, and attended with very little pain. The pin used may be straight, bent at the point, or of any curve or shape to suit the operator.

6. It is also a ready, safe method of arresting hemorrhage in recent accidents from compound fractures or other causes.

7. Many cases will fall under the observation of the practising surgeon in which its utility will suggest itself.

8. The kind of metal of which the pin or needle is made is a matter of the utmost importance, experience teaching that steel or iron produces less irritation than the more costly metals, such as gold or silver.

9. Freedom from septicæmia.

10. The great facility with which the operator could obtain a pin suitable for the compression. For one of the larger vessels it could be obtained from a lady's toilet supplies, by using any of the long steel pins with glass heads, especially those used for fastening on their hats. Their being straight in most cases would be an advantage.

11. This manner of preventing bleeding in operations about the hip-joint (exsection), shoulder-joint, or knee, will be of the greatest importance.

12. It does away with the necessity of a most important assistant.

LOW MEDICAL FEES IN THE WEST.

WE have been informed that a late distinguished specialist of Chicago would receive and treat patients for ten dollars a month, that the office-visits to a leading and world-renowned general consultant in the same city are considered by him to be worth one dollar, and that this is the fee charged by a Cincinnati specialist and professor of deservedly great repute. The *Cleveland Medical Gazette* says that in that wealthy city the medical fees are lower than in any other large city of the United States. Some physicians of large practice have fallen into the habit of charging by the week, one or two dollars being the sum asked for services rendered, perhaps daily. Some oculists fit spectacles for one or two dollars, which is less than the optician charges. One practitioner fits a pessary for the same sum, and supplies the instrument himself. An eminent surgeon charged ten dollars for examining a case of tumor of the breast. He apologized for charging so much, and offered to remove the tumor without further expense, and he did so.

A SEVERE REMEDY FOR A MILD AFFECTION.

IN a recent number of the *Gazette des Hôpitaux*, Dr. Bertillon relates how he cured a child of the habit of sucking his thumbs. He placed the boy on a chair, and, forcing him to look intently at a bright object, induced hypnotism. Then he suggested to the child that he ought not to suck his thumbs, repeating the injunction three or four times. On being awakened, the boy complained of a feeling of weight in the head. The next day he refrained from sucking his thumbs, but resumed the habit a few days later. Then he was again hypnotized, and Dr. Bertillon commanded him sternly never to

suck his thumbs again. The habit was not resumed after this, and the cure was pronounced complete.

We have cited this case merely as an illustration of a tendency, which is altogether too prevalent at the present time, to employ heroic remedies carelessly and without warrant, simply because of their novelty, when other and well-tried methods will answer every purpose. Sucking the thumbs is not such a dangerous and intractable disease that it would seem to call for the employment of a remedy like hypnotism, whose effects, immediate and remote, upon the delicate nervous structures of a young child are as yet by no means perfectly understood and appreciated.

An experiment such as the one described, in a case possessing in itself no gravity, seems to be, in the present state of our knowledge at least, one that cannot be justified. Nevertheless, there is one suggestion which it offers that may be worth considering. If it is possible to cure one habit by means of hypnotic suggestion, another, and a worse, one might possibly be broken up in the same way. In a case of masturbation, for instance, the consequences of the habit are of such a nature that almost no remedy which would be efficacious in destroying the habit could be regarded as unjustifiable. Here an heroic remedy is called for, when milder methods fail, and hypnotism offers a plan of treatment which may be well worth considering.

KREMYANSKI'S METHOD OF TREATMENT OF PHTHISIS CONDEMNED.

We referred in a recent issue to the treatment of pulmonary phthisis by inhalation of anilin oil, as recommended by Dr. Kremyanski in a communication made at the Congress of Russian Physicians, held a short time ago in Moscow. Considerable incredulity was expressed at the time by the members of the Congress as to the results obtained, but the author's claims could not be overthrown, as the method had as yet been tried by no one but himself.

It was not long, however, before the new measure was put to the test, with the result, it would seem, of very seriously discrediting Kremyanski's assertions. At a meeting of the Moscow Medical Society (*Russkaya Meditsina*) Dr. Nesteroff reported a case of pulmonary phthisis which had been treated with the ordinary remedies without any very noticeable results. When Kremyanski's paper appeared, it was determined to make a trial of his method. The patient was accordingly put upon inhalations of anilin and oil of winter-green, and died at the expiration of two weeks. Dr. Nesteroff declared himself as perfectly satisfied with this one trial, and said that under no circumstances could he ever be persuaded to repeat the experiment. His conclusions were indorsed by the Society, and a resolution was passed to the effect that the method was not only useless but was actually dangerous to the patient, and therefore unjustifiable.

This was certainly something of a set-back for Kremyanski, but we need not be too ready to accept the verdict of the Moscow Medical Society as final. Russian physicians are no better than their brethren in other lands, and are, unfortunately, not always superior to the petty jealousies which sometimes actuate the rest of mankind. Dr. Kremyanski is from Kharkoff, and possibly may not be welcomed as an instructor by the residents of the metropolis. The author claimed to have treated two patients, with well-marked pulmonary tuberculosis, by his anilin inhalations, and both patients were apparently cured. If these statements were correct, and there seems to be no reason to doubt the honesty of the author of them, it is hardly fair to condemn the method in such strong terms because of a single failure, which may not have been justly chargeable to the treatment adopted. Any method which offers even a faint hope of cure of so fatal a disease ought certainly to be given a fair trial.

BORAX IN ENLARGEMENT OF THE SPLEEN.

In a communication made to the *Indian Medical Gazette* for January, 1887, Dr. V. Richards recommends very highly the use of borax in cases of enlargement of the spleen. It was first suggested to him, he says, by a native, and he has employed it many times with great success, some of the most severe cases showing rapid improvement and ending in a complete cure. He uses the borax in addition to the iron treatment, his plan being to give to an adult from thirty to forty grains, in a lump, which is allowed to dissolve in the mouth. One dose of this size is given early in the morning, and again in the evening.

Whatever the curative value of this method may be in other hands, it certainly possesses the merit of simplicity, and can do no harm except, possibly, to the reputation of the medical attendant, during a short trial. The spleen would seem, however, to be a very accommodating organ if it will contract its dimensions at the solicitation of so mild a remedy as borax. Nevertheless the method may be worth a trial.

THE PULSE.

We have read with profound interest the Croonian Lectures on "The Pulse," by Dr. Broadbent, and have pondered with admiration over the learned comments thereon by our erudite contemporary *The Lancet*. "One has only," says this estimable journal, "to turn to the writings of Hippocrates to learn how closely and how accurately its (the pulse's) variations were observed, with much remarkable result in prognosis and treatment." Alas for the uncertainties of historical reminiscence! Hippocrates was a great physician, and it is generally thought safe to credit him with first knowing, in a crude way, of course, a little of every part of our great art. But Hippocrates, in fact knew nothing of the pulse, wrote nothing about it, and quite neglected that time-honored source of professional information. Herophilus was one of the first to investigate it, while Galen erected its study into a separate science, and fixed irrevocably upon the profession the practice of fingering the wrist as part of every medical service.

A critical examination of Dr. Broadbent's lectures on the pulse will lead one to think that its study does not at the present day give us information commensurate with the religious exactitude of the examinations made of it. In acute disease the erudite finger learns something, indeed, at times, very much, as to the strength of the heart

and the activity of febrile or inflammatory processes, but the careful physician learns still more by direct examination of the chest. The stethoscope has supplanted the *tactus eruditus* in great measure; and he would be a narrow physician indeed who drew from a condition of the pulse alone such definite inferences as to the patient's disorder as ancient authorities laid down. The knowledge which a study of the pulse gives as to the condition of the arterial walls, and as to the presence of high or low tension, is often of extreme value. There is nothing which the student should be trained with more care to observe than these conditions of the pulse. Yet even here the information is not absolute. High and low tension are relative terms, having their importance only when studied in connection with age, sex, temperament, and such pathological conditions as may be found.

Dr. Broadbent declares that he has been unable to associate any condition of pulse, as regards low or high tension, with any special vigor of body or mind or any peculiarities of temperament. Persons with a pulse of low tension may perhaps, he tells us, be longer lived; they may not wear out so rapidly; but, if better able to endure the stress of life, they are less capable of withstanding the onset of acute disease.

Dr. Broadbent denies any practical utility to the sphygmograph in diagnosis or prognosis. In this he certainly goes too far, and perhaps if he had studied his cases of high and low tension with its aid, he might have reached more definite conclusions. It is an instrument which supplements the finger, especially in this matter of high and low tension. To those who have not yet the sensitive touch that comes from long training, it may be of especial help if intelligently used.

TRANSFERRAL OF THE DYING.

For some time complaints have been made regarding the transferral of dying persons from the various hospitals of the city to Bellevue. An investigation of the facts regarding this matter shows that some reform is urgently needed, both in the interests of humanity and of good hospital management. In the past six months there were brought to Bellevue Hospital from other hospitals of this city seventy-nine persons who died within the intervals of from five minutes to four days after their admission. During the previous six months the number of cases was probably larger, so that it is safe to say that nearly two hundred dying persons were transferred by ambulances during the past year and left to swell the death-rate of our city hospital. One patient from St. Vincent's died within five minutes after admission, another from the same hospital in fifteen minutes, two within seven hours. One patient from the Presbyterian Hospital died within two hours, two within twelve hours. One patient from Chambers Street Hospital died within thirty minutes, and one each within two, six, seven, thirteen, fourteen, eighteen, nineteen, and twenty-two hours. One patient from Gouverneur Hospital died in ten minutes, and another within twelve hours after admission. A total of seventeen persons died within a dozen hours after admission, while the average time before death occurred in the seventy-nine cases was thirty-six hours.

The institutions sending these cases were: Chambers Street Hospital, twenty-nine cases; St. Vincent's, sixteen; Presbyterian, six; New York, one; Roosevelt, four; Manhattan, two; Gouverneur, thirteen; Ninety-ninth Street, eight.

The largest number of cases came from Chambers Street Hospital. This is the reception branch of the New York Hospital, and it would seem more proper for it to transfer its cases to its own hospital, which is considerably nearer, instead of taking them to Bellevue and obliging that institution to have the credit of the mortality.

The cases brought from Chambers Street lived, on an average, 1.1 day; those from St. Vincent's, 1.7 day. The Presbyterian Hospital has the most unfavorable record for its transfers of .78, or about eighteen hours. These averages, of course, refer only to the moribund. A considerable number of cases come from the city's reception hospitals, and we presume that some transfers may really be cases brought directly from the streets.

It would be unfair to charge these institutions which thus send off their dying with intentional inhumanity or a specific desire to keep their own mortality-rate as low as possible by such means. But hospital-managers should avoid the appearance of evil intention, and still more, a very manifestly inhumane practice. Indeed, some instances might be cited which appear to be illustrations of actual brutality.

The leisurely labors of Charon, as he ferried the souls of the dead across the Styx, are nothing compared with the occasional scurrying of ambulances, from all parts of the city, bearing the *morituri* to Bellevue.

News of the Week.

The China Medical Missionary Journal is the title of a new journal published at Shanghai, and edited by Drs. J. G. Kerr, J. K. Mackenzie, and E. Reifsnyder. It is, we are told, the first medical missionary journal published in heathen lands.

Medicine and Surgery at the Paris Salon.—The sensation at the Salon is a large canvas by Brouillet, representing Professor Charcot giving a lesson at the Salpêtrière to his pupils. The professor is standing at a table facing the audience. His assistant is at hand holding in his arms a woman in a hysterical attack. Another painting of a similar character, by Gervex, represents Dr. Péan giving a lesson in surgery. A female patient, under chloroform, lies on the table before him, an assistant surgeon kneels beside her counting the pulse, while a sister of charity waits for the operation to begin.

The Double-headed Boy.—At the recent meeting of the Medical Association of Georgia, Dr. W. F. Westmoreland presented a case, the account of which, as given in the *Atlanta Medical and Surgical Journal*, is as follows: "The boy had, at the lower extremity of the spinal column, what seemed to be an extra head. The outlines of the nose, mouth, and eyes were well marked. The growth was covered, except what seemed to be the face, with long curls, not unlike the hair on the head. The boy was eleven years old. He had been exhibited in all parts of the United States as the double-headed

boy, and up to within a few months before he was brought to this city had enjoyed good health. About six or eight weeks before he was brought here the extra head began to give him pain, and very soon began to suppurate. In a few weeks the boy showed well-marked symptoms of septicæmia, and when presented to Dr. Westmoreland he advised the removal of the mass. The parents objected at first, saying that they had consulted the best surgeons in the country and they had advised against any operation, deciding that it would surely produce death whenever the mass was removed. They reluctantly gave their consent, however, and the operation was performed. Dr. Westmoreland stated that the coccyx and a portion of the sacrum were involved in the tumor, or head, and had to be removed. Dissection revealed very well-marked cranial bones in the mass, with a membrane similar to the dura mater, but there was no brain-substance in the sac. He presented the boy and the tumor. The boy had entirely recovered from the operation." We regret that the history was not reported in detail, as it is highly probable that a truly rudimentary skull was present.

The Recently Organized American Orthopædic Association holds its first annual meeting on the third Wednesday in June.

The Florida Medical and Surgical Journal has retired from independent existence, and incorporated itself with the *New Orleans Medical and Surgical Journal.*

Canadian Doctors take kindly to politics. About one-eighth of the Provincial Legislature consists of physicians.

The Medical Department of the University of Pennsylvania held its Annual Commencement on May 2d, and graduated a class of ninety-nine.

The Cow-house Treatment of Consumption, devised by Dr. Saiffert of Paris, and introduced into England by Dr. Beddoes in 1799, is said by Dr. Pick (*Medical News*) to represent the idea now carried out by gaseous enemata.

The Government Yellow-Fever Commission.—We learn with pleasure that the President has appointed Dr. Geo. M. Sternberg to investigate the merits of inoculation for the prevention of yellow fever.

Early Paternity.—A correspondent of the *British Medical Journal* reports a well-authenticated case in which a boy thirteen years and four months old successfully impregnated a woman. The *Journal* states that the earliest case heretofore recorded of precocious puberty is that of a boy aged fourteen.

Dr. Daniel G. Brinton, who has been for so many years the successful editor of the *Medical and Surgical Reporter*, has severed his connection with that journal. We are pleased to learn that Dr. Brinton will not retire from the field of journalism which he has so conspicuously ornamented, but will connect himself with some other journal in the early autumn.

Professor Kocher, of Berne, will be pleased to see the announcement in a contemporary that Professor Rocher, of Berne, will attend the next International Congress.

The Coming Meeting of the American Medical Association at Chicago will not, we trust, be "hippodromed" in the extraordinary and undignified way which characterized its session a year ago. It is not a question of codes, or climate or locality, but of the self-respect, the dignity and conservatism which ought to characterize a great representative body of physicians.

The Society of the Alumni of Bellevue Hospital is composed, as we learn from a member authorized to speak, of men who have served in Bellevue Hospital as junior and senior assistant and house-physician, and who hold a diploma given them by the Commissioners of Charities and Correction and signed by the entire medical board of the institution. It has no connection whatever with Bellevue Medical College.

Landoi's Rule for Estimating the Amount of Solid Matter in the Urine.—Multiply the last two figures of the specific gravity of the urine by the number of ounces of urine discharged in twenty-four hours, and the result will express in grains the quantity of solid matter discharged. Its practical value is apparent in view of the theory that peurperal convulsions are due "not to the diminution in quantity of urea only which is excreted, but to the diminution in the amount of all the solid constituents which are in solution in the urine."

Railway Mortality.—The returns of accidents and casualties reported to the Board of Trade by the several railway companies in the United Kingdom during the year 1886 show the total number of persons killed and injured in the course of public traffic during 1886, to have been 938 killed and 3,539 injured.

Obituary.

E. DARWIN HUDSON, JR., M.D.,

NEW YORK.

The death of Professor E. Darwin Hudson, Jr., of this city, which occurred on May 10th, was most sudden and unexpected. It is not only a sad blow to his family and numerous friends, but it is a serious loss to the profession of this city and, we may add, of the whole country. Dr. Hudson was one of our most active workers, and few are aware of the amount accomplished by him in promoting the success of the societies and school with which he was connected. After a good many years of untiring industry, he had begun to reap in full the well-deserved rewards of reputation and remunerative practice. And it is a sad and bitter reflection that just at this moment, when life held out its brightest promise, he should be suddenly taken away. Dr. Hudson was a man of sound and extensive knowledge, of ripe experience, and excellent judgment. He was affable and kindly in manner, and reached his position in the profession making only friends of his competitors and rivals. Yet he was a man of decided force of character, as his career abundantly showed. His contributions to medicine were not very numerous, but what he did was always well done, and his written contributions always attracted attention and drew forth discussion. His little work on "Physical Diagnosis" is a model of clearness and compactness. Dr. Hudson was identified with the prosperity of the Polyclinic and of the Academy of Medicine. In his earlier years he was Professor of Medicine in the Woman's Medical College of this city. Dr. Hudson was born at Northampton, N. Y., in 1843.

Reports of Societies.

THE SIXTH GERMAN CONGRESS FOR INTERNAL MEDICINE.

Held at Wiesbaden, April 13, 14, 15, and 16, 1887.

PROFESSOR KORTE, OF BERLIN, IN THE CHAIR.

[Special to THE MEDICAL RECORD.]

(Continued from page 529.)

THURSDAY, APRIL 14TH—SECOND DAY—MORNING SESSION.

After the transaction of some routine business PROFESSOR NOTHNAGEL, of Vienna, presented a paper on the subject of the morning session, viz.,

THE LOCALIZATION OF BRAIN DISEASES.

The speaker opened with a reference to the great and wide-spread interest taken in this subject. We have chiefly to thank Fritsch, Hitzig, Munck, Meynert, and Flechsig for their labors in this direction. This question belongs to the most complicated and difficult in all pathology. The subject was discussed in a most scientific and careful manner.

PROFESSOR NAUNYN, of Königsberg, read a second paper on the same subject, which agreed in substance with the previous communication.

DR. H. CURSCHMANN, of Hamburg, opened the discussion with some practical points from his own experience.

PROFESSOR HITZIG, of Halle, thought that from the nature of the subject it was only possible in a small way to come to a complete understanding of it. Since Broca's observation that disturbance of speech occurred almost without exception after right-sided paralysis, that is, left-sided brain disease, the fundamental question is, in general, on the ground of pathological observations, Can a localization of the cortex cerebri be made? This question, as far as the human brain is concerned, may be answered in the affirmative. Both essayists pointed out the best method of solving the problem which the clinical material could impart. Now, if a disturbance of function is always found with a lesion of a certain place, and never without this lesion, and if this lesion never occurs without the disturbance, then the conclusion is plain. This circumscribed spot must be the seat of the function in question. The speaker concluded with the following statements:

1. The disturbances of vision, which till now have been observed in connection with disease of the cortex are the following: (*a*) Hemiopia; (*b*) complete blindness; (*c*) psychological blindness; (*d*) disturbance of the sense of color; (*e*) subjective perception of light and of faces. (*a*) treats of blindness mostly of the lateral fields of vision; light-impressions are not felt in general. Under (*b*) the blindness, which is constituted only by double-sided foci, is described as double-sided hemiopia. The psychological blindness is not confined to those suffering from mental disease with general paralysis. In these cases the patient sees, but may not appreciate the retinal impression. The optical pictures are lost to him; he no longer combines ideas with them. Upon the ground of clinical and anatomical experience, it can be said with freedom: The appearance of continued cortical hemiopia is dependent upon the lesion of the cortex of the left lobe and of the left occipital depression. If the lesion occurs on both sides, then complete blindness occurs. For mental blindness we should seek an anatomical groundwork in the occipital lobes.

2. Motor cortex paralysis, for example, of the extremities, is the result of lesions of the gyri centrales and of the lobulus para-centralis.

3. The paralysis of the so-called muscular sense comes from lesions of the temporal lobes.

PROFESSOR NAUNYN directed attention to the localization of the aphasic disturbances in the cerebrum. By aphasia one understands those disturbances of speech which do not simply depend upon the general weakness of the mind nor upon paralysis and weakness of the vocal apparatus. The speaker described three great groups of aphasia: (*a*) Motor; (*b*) sensory, with word-deafness; (*c*) uncertain. In the motor group the patients are unable to form the words, but this is not in consequence of paralysis of the muscles of speech. The second group includes those cases in which an evident difficulty of understanding words, or "word-deafness," is present. The third group embraces the whole number of those very different cases in which we find as characteristics either the difficulty of forming words or the inability to understand words. The motor aphasia is located in the region of the convolution of Baroca, the sensory aphasia in the region of the temporal lobe of the cerebrum. These aphasias also depend upon the lesions of the cortex just mentioned. The cases of the third group, which generally appear to be more developed forms of the first two, depend upon a lesion localized quite near to those of the latter.

PROFESSOR ADAMKIEWICZ, of Cracow, read on the subject

THE CURE OF NEURALGIA BY MEANS OF CATAPHORESIS.

The reader had already, in a former article, expressed the opinion that by means of an instrument devised by himself and called "diffusion-electrode," chloroform could be forced through the skin until the patient was thrown into the deepest cataphoresis. He then reported the results obtained by this procedure in the treatment of neuralgia. The diffusion-electrode should be connected with the positive pole of a constant battery, and placed upon the painful part before the current was closed. Now the current should be closed and gradually increased to seven milliampères. It should be held at this height for two minutes, then slowly brought down to nothing. From this kind of an application the speaker had never seen any evil sequences. He had never observed the formation of eschars, but had found that the cataphoresis cured the neuralgia in all his cases, and that the cure followed more promptly the more recent the case. The nerves having a superficial course he found could be cured much easier when the conditions were favorable. One sitting is enough to completely remove the complaint. In chronic neuralgia the cataphoresis cuts short the duration of the attack, weakens its intensity, and can, for a longer or shorter time, bring it under control. Those neuralgias which depend on a trouble which cannot be reached by the cataphoresis are very unfavorable for its definite action.

PROFESSOR A. FRAENKEL, of Berlin, delivered an address on the subject of

THE ETIOLOGY OF TYPHOID FEVER.

This was discussed for a short period with considerable vigor. The discussion was concerning the infectiousness of the disease.

AFTERNOON SESSION.

PROFESSOR VOGEL, of Munich, read a paper on

THE PATHOLOGY AND TREATMENT OF WHOOPING-COUGH.

This disease is classified by Gerhardt among the infectious diseases, yet the contagion of whooping-cough is of another nature than that of the acute exanthemata. As concerns the pathology, the great clinicians of the last century presented a gastro-pathological theory. In the beginning of the present century the neuro-pathological theory had many followers, but this also fell to the ground as unsuccessful as was the attempt to prove whooping-cough to be a simple bronchial catarrh. There now remains no doubt that it comes under the list of infectious

diseases. In the pneumonia following measles and whooping-cough great numbers of microbes were seen by Thaon in the pus and lung-cells of the exudated matter, and, indeed, in the pneumonia of pertussis he had found diplococci and bacilli in greater numbers than in diphtheritic pneumonia. In the case of a nursing-child whooping-cough is a dangerous and pernicious disease; in older children the course of whooping-cough is favorable throughout. In an epidemic in Wurzburg 52 children under one year were taken ill and 13, or 25 per cent., died; 248 were attacked between one and five years, and 12, or 4.8 per cent., died; between six and fifteen years, 87, of whom 1, or 1.1 per cent., succumbed. The author lamented that the mortality tables followed the age so closely, notwithstanding the plan of treatment followed. The remedies recommended for whooping-cough are of two great classes,

ANTISPASMODICS AND DISINFECTANTS.

In treating the spasmodic cough by narcotics one resigns every chance of shortening the process; opium and all its preparations should not be given for any length of time continuously; however, a small dose of opium or morphia is a great relief to children who have passed sleepless nights. A combination of cannabis indica and belladonna is especially recommended by Vettersen. Of 116 children so treated a favorable result was recorded in 33; of these, 30 were completely cured in from eight to fourteen days. Prior recommended the painting of the oral cavity with a solution of cocaine of a strength of from 10 to 20 per cent.; the application of cocaine is not entirely without danger, however.

THE ANTISEPTIC TREATMENT

strives to shorten the attack by destroying the germs of the disease. The speaker mentioned the different modes of treatment by residence in gas factories, inhalations of carbolic acid, etc. Concerning

PSYCHICAL TREATMENT

nothing new has appeared in recent literature. No followers have been found for the opinion that whooping-cough can only be cured by the rod, fortunately for the poor little patients.

Professor Hagenbach, of Basle, read a second paper on this subject. He gave a large number of statistics; 240,000 children have the whooping-cough every year in Germany; in Basle, 1,000 per year, with 12 deaths. The mortality is on the average four or five per cent. Toplitz reports the mortality from this disease among the children of Jolichnic, in Breslau, in the years 1875 to 1885, as 7.9 per cent. In Basle during the last eleven years the mortality among children under one year has been 26.8 per cent.; from one to two years, 13.8 per cent.; two to five years, 3 per cent.; five to ten years, 1.8 per cent.; ten to fifteen years, 1.8 per cent. These figures show that whooping-cough is a serious disease in the tender years of childhood.

WHAT IS WHOOPING-COUGH?

The recent investigators are about all united that it is an infectious disease. It comes epidemically, seldom sporadically. In large cities it is endemic and contagious. In whooping-cough we have a catarrh of a certain part of the mucous membrane of the respiratory tract, which is dependent upon the lodgment of fungi. At these places, through irritation of the ending of the superior laryngeal nerve, attacks of coughing are excited by reflex action. Professor Hagenbach then discussed the question whether we have to deal with a local or a general infection. The disease is most frequent in the first year of life, and is found with rarity in the first months. The susceptibility is great up to the tenth year; after this age it becomes less. It is contagious in the first and second stages; so long as mucus is produced the disease may be carried. Outside of the human body the contagium seems to be unable to exist for any length of time. The speaker then discussed the question of

PROPHYLAXIS.

Schools for small children should be carefully watched, and children with suspicious coughs kept away as long as they cough in paroxysms. The expectorated material must be carefully removed; if the disease spreads the school should be closed. The moving of children infected with whooping-cough to various places for change of air is often the cause of an epidemic in places free from the disease.

Dr. Michael, of Hamburg, discussed the subject and recommended a method used by him, consisting of inhalations into the child's throat. In more than one hundred cases so treated he had more or less improved seventy-five. In twenty-five cases he had no success at all. The speaker laid more stress upon the qualitative improvement of the cases than on the shortened duration.

Professor Heubner, of Leipsic, considered the character of the disease to be that of a virulent catarrh, and not a blood infection. He agreed with the former speaker in thinking it possible to render these attacks fewer and lighter, and eventually to cause the shortening of the disease and its cure.

Dr. Schliep, of Baden Baden, recommended the treatment by the pneumatic cabinet, which he had used. The increased pressure of air in this cabinet acted mechanically as a sedative on the mucous membrane. He found from twelve to twenty sittings sufficient to cure a child suffering from whooping-cough; as a further remedy he recommended an emulsion of turpentine. He also had had success from burning sulphur in the room.

Dr. Sonnenberger, of Worms, advised the use of antipyrin. He had used it in an epidemic in Worms and vicinity with success, and claimed that it rendered the attacks milder and shortened their duration.

Dr. Cohen spoke of the favorable results from inhalations of bromide of potassium, and also of the use of the musk preparations.

Friday, April 15th—Third Day—Morning Session.

Professor Unverricht, of Jena, presented a communication on

EXPERIMENTAL EPILEPSY.

The lower half of the cortex of the brain contains the centres for the occurrence of epilepsy. Irritation of the cortex will cause attacks of epilepsy. The speaker knew, from experiments he had carried out upon a dog, the importance of the motor region for the muscular spasms.

Professor Rossbach, of Jena, read a paper describing

A BREATHING-CHAIR FOR EMPHYSEMATOUS AND ASTHMATIC PATIENTS.

While till now it has been necessary to use manual treatment of the thorax in order to lighten the severity of asthmatic attacks, a stool had been invented by a patient of the speaker which enabled him to breathe compressed air without manual aid. The patient takes a seat, and buckles about his chest a girth which is made fast to the chair; on both sides of the chair are arms, which the patient moves forward, and which movement tightens the girth four centimetres. By means of this continuous moving of the arms of the chair the patient is enabled to relieve himself. The professor had used such a stool six months in his clinic, and had improved several cases. The advantage this chair has over manual treatment is that through this band the whole thorax is regularly compressed, which is impossible with the hand. Besides, the physician or attendant would not be able to carry out the manual treatment for more than half an hour, while the chair can be used as long as desired. Also this instrument is always at hand, for attacks in the night or any time when manual aid may not be available. The

professor exhibited the chair, and presented the patient who had invented it to the Congress.

Professor Schreibe, of Königsberg, related how he had attained the same results by means of elastic corsets.

Professor Litten, of Berlin, next read a paper on the

CONNECTION BETWEEN DISEASE OF THE STOMACH AND CHANGE OF POSITION OF RIGHT KIDNEY.

The fact that distention of the stomach occurs in connection with dislocation of the kidneys, the so-called wandering kidneys, is not new. The only question is, if this stands in a causative relation to the other. The change of position of the kidneys is dependent on mechanical causes; in women it is often occasioned by too tight lacing. The speaker then related such cases of dislocation as had not yet appeared in the current literature. He had made the observation that the ectasia of the stomach occurs frequently in connection with dislocation of the kidneys in laborers, masons, and others whose mid-day meals often consist of indigestible food and are eaten in a very short time. He only found two women among his patients who were able to take their meals quietly. In 17 out of 28 cases of stomach distention observed by him, dislocation of the kidney was present; this brought him to the belief that the distention of the stomach is the cause of the dislocation of the kidneys. In the other cases the renal arteries are probably too short, so that on this account the kidney could escape. The greater or less mobility of the kidneys depends upon the greater or less tightness of the arteries. In closing, the speaker went into detail concerning his findings in post-mortems of such persons as had distention of the stomach with wandering kidneys.

Professor Nothnagel, of Vienna, opened the discussion. He was acquainted with the frequent coincidence between distention of the stomach and dislocation of the kidney, but disputed, however, the causative connection. He had in a period of three months found sixteen such cases. The stomach-distention in many instances was primary, the dislocation of the kidneys secondary. Most cases of dislocation occur in lean, broken-down, nervous women. The speaker then dealt with the treatment of this disease. He placed lean persons first on the malt cure, then placed a cushion over the kidney to hold it in position, and a waist over the cushion which covers the whole body.

Afternoon Session.

Professor Finkler, of Bonn, read a paper entitled

OBSERVATIONS ON THE MODE OF CONTAGION AND TREATMENT OF TYPHOID FEVER.

Modern investigations concerning the nature of the infective germs show how the infectious diseases reveal themselves. In some there is a direct carrying from a diseased to a healthy person, while others are not generally spread, but are confined to special place. Among the pure contagious diseases are small-pox, scarlet fever, diphtheria, etc.

A pure miasmatic disease is represented by malaria. Between these two we now place a third class, termed contagio-miasmatica, to which we refer cholera and typhus abdominalis. It is partly believed that the latter is not carried directly, but the germ coming from a diseased person attains a certain ripeness in the soil and is then able to generate the disease in another person. The knowledge of the quality of bacteria, and especially of those which would seem to be the generators of typhoid fever, goes to show that this indirect spreading does occur. It appears this is the rule, and direct infection is entirely denied by many. Recent observations prove that the infection is carried by many different kinds of vehicles. An excellent example is the epidemic in Mayence in 1884, which was undoubtedly carried by artificial mineral water (according to Dr. Helwig).

Typhoid fever is not confined to certain parts of the earth; it can be carried into a city like Wiesbaden, otherwise so favored as to health, and disturb this security. From numerous examples, we know that if the nest in which the germs are resting is destroyed the epidemic will be cut off for all time; and from this fact it must be believed that there is a difference between the medium which spreads the disease and the source of infection.

Professor Fleischer, of Erlangen, gave an account of some experiments bearing on the

PATHOLOGY OF THE KIDNEYS.

They consisted of numerous experiments on a dog.

Dr. Kühne, of Wiesbaden, read a paper on the appearance of

SPIROCHÆTA FORMS OF THE COMMA BACILLUS

in the tissue of the intestine in cases of cholera, with demonstrations of different fluorescent preparations. The speaker had examined a great many specimens from the epidemics of Paris and Palermo, when he accidentally came upon this variety. After discussing the comma bacillus *in extenso*, he closed by recommending his method of coloring to find the bacillus in the tissue. He then gave different methods of his own to bring to view the bacilli in the internal organs in typhoid fever, lepra, etc.

Dr. Fraenkel, of Dornheim, read a paper on

THE PERMANENT INHALATION OF FRESH AIR,

a treatise on the prophylaxis and therapy of lung-affections.

Professor von Mering, of Strassburg, followed with a paper on

DIABETES MELLITUS.

Dr. Cahn, of Strassburg, then presented a communication on

THE ACIDS IN CARCINOMATOUS STOMACHS.

This was followed by an earnest discussion, taken part in by Professor Riegel, of Giessen; Professor Fleischer, of Erlangen; Professor von Noorden, of Giessen; Professor von Mering, of Strassburg; and Dr. Stückel, of Cologne.

Saturday, April 16th—Fourth Day—Morning Session.

The Secretary, Dr. Emil Pfeiffer, of Wiesbaden, read the reports of the various committees, saying that the Executive Committee had chosen Wiesbaden as the place of the next meeting. The number of members at the last meeting was 209; 7 died, leaving 202 at the beginning of this Congress; 22 new members had been added, making a total now of 224. The number of those present at the Congress last year was 234; this year, 249.

Professor Liebenstein read a paper on

MUSCULAR EXERCISE OR QUIET FOR HEART DISEASE.

After enforcing the dictum of Professor Hoffmann, "Forbearance and exercise," the author said that the majority of the clinicians and physicians held out firmly against a more active treatment of chronic heart disease through exercise of the heart-muscles, and insisted that, above all things, all acute cases, also those where an over-distention of the heart had occurred, must be handled with care. Quiet does not, however, improve the chances of the patient, while a reasonable nourishment, combined with exercise properly carried out, causes a strengthening of the heart-muscles. In all chronic

cases we should change from quiet and care to the endeavor to strengthen the heart-muscles by exercise. On the ground of his rich experience the speaker felt sure that strong yet quiet movements, with quiet exhalations of air, work toward strengthening and slowing the action of the heart, as has already been made known by Schott, of Rauheim. In cases where there is failure in complete contraction, the distended ventricle is never entirely emptied and the heart-muscles become weary, and in the end incapable of performing their duty. Then by means of quiet but energetic muscular exercise the heart is strengthened, stirred up to effectual contraction, and, at the same time, the diastole grows in consequence of the slowing of the pulse. The increase of the arterial blood-pressure acts on the vagus centre, more of the distended blood is forced out of the heart, and thereby the cause of the dilatation removed. Further, the rapidity of the blood-stream increases in consequence of the increase of the arterial pressure. Then, after a number of strong contractions, this acceleration extends to the capillaries and the veins, and a better distribution of blood takes place throughout the entire vascular system. The improvement in the quality of blood lightens the work of the heart-muscles, and in consequence of the stronger stream in the coronary arteries the weakening remaining products are more promptly removed. For patients in the first stages of fatty heart, or with well-compensated heart-failures, every form of German or Swiss mountain-climbing can be recommended.

The speaker warned his listeners against over-exertion, and said that each performance should be followed by a sufficient period of repose. Those cases of failure, however, in which there is no compensation or in which it has been lost, must first pass through a period of quiet and forbearance, and then, by well-measured work, we may commence to improve the action of the heart. The watchful control of the physician is necessary, and only the most quiet forms of muscular labor are fitting. The Swedish method improved by Schott, brief and under medical control, interspersed with pauses for quiet, is to be recommended. On the ground of his experience of the last few years the speaker advised the Oertel-cure for chlorotics; but, above all things, it must be conducted with the greatest care, and its execution must not be left to the patient himself. The heart should not be allowed to be more rapid in its action than the lungs can follow, for deep, quiet breathing has a lightening influence. He closed with the wish that the therapy of chronic heart disease would be placed on the list of subjects for discussion in the Congress.

Dr. Theodore Schott, of Bad Nauheim, recalled the fact that his brother, now dead, had recommended strong but quietly carried out movements, with regular breathing, as a method of cure in chronic heart disease. The mountain-climbing method of Oertel the speaker could not sanction. It is useful only for a very small number of patients; we cannot say when we may commence with this treatment or how high or far the patient shall be allowed to climb. There is always decided danger connected with this plan of mountain-climbing, and the speaker had seen harm done to patients treated in this manner by Oertel and his disciples. It is better far to first strengthen the heart-muscles by means of baths, gymnastics, etc., so that it can stand the greater labor required for mountain-climbing. In other cases the danger incurred by climbing is too great; the indications are to be determined by the pulse-curve.

Professor Leyden, of Berlin, remarked that the mode of treatment originated by Oertel had given valuable therapeutic material and was also an advance. He advised great care in deciding which cases of heart disease could be improved by the gymnastic exercises, and when they are to be used. In light cases in youth, in which a valvular insufficiency can be compensated, careful gymnastics may be used. The President then recalled the fact that the method of Stokes had met with great objections, and he was of the opinion that in the very difficult question,

WHAT INFLUENCE HAVE MOVEMENTS, GYMNASTICS, AND MOUNTAIN-CLIMBING ON THE HEART?

the deductions are still arbitrary in many points. He closed with the expression of the hope that in one of the congresses not far in the future there would be sufficient material on hand to explain this weighty and difficult subject.

Professor Schultze, of Heidelberg, reported numerous cases of

ACUTE DISEASE OF THE CENTRAL NERVOUS SYSTEM,

in which the general anatomical changes fail and we must decide on a diagnosis of meningitis.

Professor Friederich Mueller, of Berlin, read a paper on the

RESORPTION OF FOOD IN CERTAIN DISEASES.

Professor Leyden then made a few short closing remarks, in which he expressed great satisfaction with the work of the Congress and hope for its future advancement.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY.

A. R. Robinson, M.D., President, in the Chair.

Stated Meeting, March 16, 1887.

Dr. J. Lewis Smith read the paper of the evening (see p. 542), entitled

A CONTRIBUTION TO THE STUDY OF CEREBRO-SPINAL FEVER.

The paper being open for discussion, Dr. R. C. M. Page said: "I have had but little experience with the disease; but I remember that in February, 1870, I was called to see a patient in a basement in Rivington street, a boy seven years of age. I found his temperature 107°. There was hemiplegia and delirium, with suppression of urine. It was in my earlier years of practice, and I did not exactly know what was the matter. Upon inquiring of the mother, she told me that the child had fallen from a chair at noon and hurt its back. She ascribed the whole difficulty to that, which, of course, I thought was a mistake. I prescribed for the patient, and went back to my office. About midnight I was called again to see the boy, and found him dying. I never knew exactly what was the matter with that patient; but the whole neighborhood was full of scarlet fever, and several of the children in that basement about a week after had scarlet fever, although there was none of it in the house at that time. I remember signing the certificate as of death from scarlet fever, but have since thought it might have been a case of cerebro-spinal fever. It may be interesting to inquire whether there is any connection between these two diseases. I have never had a case of it since."

Dr. J. H. Fruitnight said: "This subject is a very important one, and those gentlemen who have lived through epidemics of this disease will be able to give us much enlightenment in regard to it. I have seen at least eighteen cases here and there—three adults, and one case of pulmonary variety; the others were ordinary cases. I have never had any experience in epidemic cases, but recollect having seen one case, of a young lady, where I was struck by the appearance of the eruptions. They were all over the body, particularly over the abdomen, and about three or four inches in diameter. In the sporadic cases I have never seen any eruption whatever, and it seems to me that there must be a difference between the disease in its sporadic and epidemic forms. In complication with other diseases it again differs from either the sporadic or epidemic form. As such it is rather a local trouble, and the other diseases are *sui generis*. Dr. Smith has properly said that in cases occur-

ring here and there no contagion exists; but in the epidemic form I certainly think there is contagion. In one case, of a child who died within three hours, inquiries were made by the health officials later, and they formed the diagnosis, although no autopsy was made. The temperature in that case ran to 108°. As a rule, the temperature need not be regarded unless it rises above 103°. As regards the frequency of the disease at the various ages, with increasing years the tendency to the disease decreases; it is essentially a disease of infancy and early childhood. Most of my patients were from one to eight years of age.

"The author of the paper gave some statistics relating to the various wards of this city which are a little misleading. For instance, the Nineteenth Ward includes a vast amount of territory; and, again, the great proportion of cases occurring in the Seventh Ward may perhaps prove that where there is overcrowding the disease may result from that cause, for in that ward the population is more dense than on any equal portion of territory on this continent."

Dr. C. A. Leale said: "I can safely say that Dr. Smith has carefully observed more cases of cerebro-spinal meningitis than any other living physician. My first observation of this disease was in 1864, when I was instructed by the Medical Department of the United States Army to investigate the cause of cerebro-spinal meningitis as it commenced to appear in Elmira, N. Y. We had admitted to our ward a boy fourteen years of age, of whom I made a very thorough physical examination without arriving at a diagnosis. I found that he was then suffering from very high fever; his temperature was then up to 107°. He had a rapid pulse, indicative of feeble heart-action. His lungs revealed nothing abnormal. His kidneys were normal, as far as the examination of the urine indicated. There were none of the eruptions of typhoid fever, nor the usual characteristics of the disease locating itself in the intestines. I left the hospital for three or four hours, and on my return was met by a number who said that there was a general stampede there. I found this boy covered with spots as large as pigeon's eggs, and almost black. He had purpura hemorrhagica and was delirious. I did not know what such a change in a few hours could mean, and sent for consultation with the post-surgeon, who was familiar with the diseases of the Chemung Valley, having practised largely in consultation in Pennsylvania and Southern New York. He pronounced it a case of cerebro-spinal meningitis. This boy had very severe symptoms. He had paralysis below the waist. His anus was paralyzed. He passed his fæces involuntarily, and his urine passed from him without any power to retain it. The dark spots continued about two weeks, at the end of which time he died from exhaustion, never for a moment having been restored to consciousness. This was the first case in the hospital, although we had a large number of cases of measles occurring among our recruits coming from the country towns. I went to the place from which this boy was brought, and found in the outskirts of the city a large building, formerly used as a warehouse, and which had been recently converted into barracks. The cracks in the building were so frequent and large that streaks of light here and there could be seen, and there were draughts from all directions. Bunks had been placed in this building one above the other, so that I had to climb up eight or ten to reach the one from which this boy was taken. The theory current at that time as to the cause of rubeola in the army was that it was due to a peculiar fungus found in the straw. Our recruits slept on straw apparently fresh, and everything about the building seemed to be in as good a sanitary condition as possible, with the exception of the risks from exposure. The barracks were in a bleak, exposed place, and the boy undoubtedly was severely chilled in this loft. We had no recurrence of the disease during six months of duty at that station, although besides the inhabitants of the place there were ten thousand of our own troops and ten thousand Southern prisoners. This case arose *de novo*, as if it were of an acute specific origin, and after showing itself in this extremely violent form it ended.

"Another very important observation in regard to the etiology of this disease was made by me in the upper part of this city some years ago; it was in that part where the new streets had been laid out, forming, as it were, bridges across deeply sunken lots. The man in whose family this occurred had built a temporary house on a leased lot, and had his yard at least twenty feet below the level of the street. This man was a carter, who had been prosperous down-town and moved up there to have a larger place for his horses. He had six horses and four children, but one of the children was away from home. His six horses died of convulsions in that place within a period of four weeks. During their convulsions they were very violent and kicked out the sides of the stable. All the children at home died—one from malignant sore throat, probably diphtheritic, and two of what I then styled cerebro-spinal meningitis. All had been exposed to violent currents of air, as it was at a season of the year when severe impressions upon the nervous centres would be made by the sudden changes of temperature.

"Another instance occurred in a wealthy family living near Fifth Avenue on Fifty-first Street. The eldest son, about eight years of age, a precocious child, came home one cold morning with his nurse and complained of being so cold at the back of his head and neck that it was a long time before he could be made comfortable. This child had all the symptoms of cerebro-spinal meningitis. He lingered about sixteen or eighteen days and died from exhaustion.

"The case mentioned by Dr. Fruitnight was that of a school-teacher who passed through a severe form of the disease. She had very black spots, became blind and deaf, and about two weeks after the disease began she had gone through all the usual symptoms—high fever, dry tongue, cyanosis, etc. At the end of about three weeks her sight and hearing returned, but she always complained of an intense headache. On returning to her duties as teacher, she could not bear the ordinary noise made by the school-children. She found herself unequal to the position, but as it was her means of support I encouraged her to keep on; she did so until one day, when dismissing her school at twelve o'clock, she threw up her arms, gave a sudden shriek, and before anyone could reach her she was dead. An autopsy was made: As to the brain, a large amount of old exudation was found upon the arachnoid membrane; at the circle of Willis there was a rupture of a degenerated artery, and the sudden death was due to apoplexy.

"I wish Dr. Smith had presented more information in regard to the pathogenesis of the disease; whether he considers it a disease *per se*, or whether the result of some other disease. Is it due to the suppressed eruptions of rubeola, scarlatina, or even syphilis? The author calls attention to a foreign belief in the microbic theory of its origin. I think we find a great many micro-organisms in all diseases attended by high temperature, and in which disorganization of blood-corpuscles allows some atmospheric micro-organism to locate itself in the blood."

Dr. W. M. McLaury said: "During the time of my connection with the Northwestern Dispensary I saw a good many cases of cerebro-spinal fever. Among colored people the disease was always fatal, while among white patients recovery was always slow.

"In this city the disease is much more prevalent among children from four to fourteen years of age than among adults. In connection with this I was surprised to learn from the statistics cited in the paper that so few cases of cerebro-spinal meningitis have been reported from the Southern States. This is probably owing to imperfections

in the statistics from those States; whereas the disease is presumably as prevalent among these as among the Northern and Western States.

"During a part of the time of my connection with the Northwestern Dispensary there was an epidemic of what was then known as relapsing fever, and some of those cases were diagnosed as cases of cerebro-spinal fever; but whether so or not they were very tedious in their recovery."

Dr. S. H. Dessau said: "The point referred to in the paper regarding the alliance of cerebro-spinal fever with other diseases, such as pneumonia, is a very important one. It reminds me of cases of typhoid fever which presented considerable difficulties in diagnosis in their early stages. I have never met a case of cerebro-spinal meningitis as a primary disease, but these cases so closely resembled what I considered at the time was cerebro-spinal fever that it required time to settle the diagnosis. One case which was a source of disappointment occurred in my service at the New York Hospital, where the patient died. An autopsy revealed the characteristic lesions of typhoid fever."

Dr. C. S. Wood said: "It may be proper at this time to compare our present epidemic with one of the first we have any knowledge of in this country. In drawing that comparison an evident difference occurs. Dr. Smith has referred to the epidemic form which spread all over the country. It commenced here, although not as severely as some epidemics which we have had. In 1866, after the war, I was invited by some members of the Board of Health to confer about this disease, which was beginning to show itself in New York City. I may be permitted to refer to the connection supposed to exist, as the author of the paper has stated, between these different forms of disease.

"In Broome, Chenango, Cortland, and some of the western counties of the State, in 1847, there was a severe epidemic of dysentery, from which large numbers died. At the end of three years the disease had nearly disappeared. That was the only epidemic in the country at that time. In 1851 a second epidemic of dysentery occurred, extending all over the country among the farmers, and it even extended to the people living in the best hygienic conditions. After the subsidence of this epidemic, which was less severe than the former one, cerebro-spinal meningitis followed. This also occurred not in towns as much as in the surrounding country, and dysentery accompanied it. These two diseases progressed side by side for three full years with large fatality. In nearly all the severe cases the disease assumed the epidemic character of spotted fever. When the epidemic had begun to decline we saw very few cases of spotted fever, just as now, because the epidemic when on the decline is much less severe.

"At the time when the complications were, as stated by Dr. Fruitnight, of a pulmonary character, I recollect a number of cases where men would go about their business in the morning, would return in the afternoon with a chill, and become delirious before midnight.

"After the first year the number of cases did not diminish as did the severity of attack. In this epidemic there were comparatively few people attacked; the patients were, in large proportion, adults from fifteen to thirty-five years of age. There was no connection, so far as could be observed, between the disease and pneumonia.

"In New York City the disease is largely among children, just as is diphtheria. They are, of course, more susceptible to it, and if the epidemic is on the decline they would be the first attacked. I have seen here comparatively few adult cases of cerebro-spinal fever; perhaps one dozen altogether.

"It is always convenient to attribute disease to sewer-gas and defective drainage, whereas in the most severe epidemics I have ever witnessed there was no sewer-gas within twenty miles. In the epidemics here alluded to—from 1853 to 1856—cases attacked lived on rolling ground, on the hills, in the valleys, and beside running water. One case would occur in one locality and another perhaps five or six miles away, there being no connection whatever between them. Having seen those two severe epidemics of the fearful disease, with their heavy mortality, I have very grave doubts about the etiology usually attributed to it in this city. I do not think sewer-gas or defective drainage has much to do with its production. It seems that when one epidemic declines another succeeds; and whence it comes and where it goes we do not know. We are apt to attribute everything to bacteria and micro-organisms; but I am strongly of opinion that those organisms are rather the effect of disease than its cause."

In reply to the inquiry of Dr. Baruch, Dr. Wood stated that he did not regard the disease as contagious or infectious.

Dr. C. L. Dana said: "One question alluded to by the author of the paper is of particular interest, viz.; whether some of the cases that are reported as cases of cerebral paralysis in children are really not cases of cerebro-spinal fever. The suggestion is new to me, and is one I shall be glad to think upon and study. We have, as yet, however, no very great evidence that these paralyses are really due to that trouble. Almost all the cases of cerebral paralysis in children are hemiplegic, and this limitation of the lesion in most of the cases would preclude the possibility of cerebro-spinal fever.

"Cerebro-spinal fever is the precursor of chronic nervous disorders that are often very intractable. The fact of their origin in cerebro-spinal fever is a help to us in throwing light on the pathology. I have had cases of affection of the upper part of the cord especially, following cerebro-spinal fever. The patients were women, and they had severe pains and other symptoms characteristic of that disorder; and the fact that they once had a meningitis justifies us in assuming that many of the cases of spinal irritation are cases of chronic thickening of the meninges, with hemiplegia and irritation of the nerves. In spinal meningitis the lesions are in the upper part of the cord, and that would explain why, in those cases that I have seen, the spinal irritation is mostly an upper dorsal one, while the symptoms are sensory and not motor.

"The most common complications are such as Dr. Peck might speak upon—deafness and loss of sight. I am interested in the nature of the fever because I have been working more or less in the laboratory, and have had opportunities to see the micrococci found in investigations of this disease. It has been stated by bacteriologists that the micrococcus is pathogenetic of this disease, but on this point further research is necessary."

Dr. B. Thompson said: "I have not seen in my cases of cerebro-spinal fever any spots, and am glad to hear Dr. Leale and Dr. Wood speak of the microbes as being the effect rather than the cause of the disease. The statement has been made that it has occurred in the country where the drainage has been perfect. In this respect it resembles typhoid fever, some of the most typical cases of which I have seen in the mountains of West Virginia. While sewer-gas no doubt plays an important part in many of the diseases occurring in our cities, increasing their severity and possibly the death-rate, still I do not think they are always to be regarded as prime factors in their etiology."

Dr. Charles E. Young said: "I have a case at present under observation which has been diagnosed as cerebro-spinal meningitis. My experience with the disease has been limited to four cases. Two of these were of the epidemic variety, and were seen in the summer of 1882. They were children in the same family, and both recovered. Their temperature went up to 103° and 104°. Another was that of a woman, twenty-six years of age, who had the characteristic eruption and tympanitis. The temperature in her case was at no time above 102°. The fourth case may come under the head of some of those spoken of by Dr. Smith as belonging to a class of cases

often diagnosticated as simple paralysis. This was a child with temperature running up to 104°, 105°, and 106°. The attack began with most obstinate vomiting, which continued for several days; shortly afterward, before the death of the child, there was slight rigidity. No eruptions whatever occurred in this case."

Dr. H. D. Chapin said: "I desire to mention a case of cerebro-spinal fever complicated with syphilis. The individual had syphilis, and while this was in active progress the patient took cerebro-spinal meningitis and died."

Dr. Robert Newman said: "The case of the schoolteacher related by Dr. Fruitnight and Dr. Leale is interesting. It shows that in cerebro-spinal meningitis there may be an apparent recovery of the patient, while the result of the inflammation of the meninges may continue and cause an ailment which finally ends in death. I know of a similar case where death was not so sudden. The patient recovered slowly, and was particularly benefited by an ocean voyage. The fresh air had a great deal to do with making him feel better. As soon as the patient returned to New York, to the old locality where the disease was contracted, there were symptoms of depression, with piercing headaches, which finally ended in death in one night. In such cases an ophthalmoscopic examination of the eyes would be important, in order to see what changes have taken place there. I was in hopes that Dr. Peck would bring out these points and tell us about these examinations. In regard to the etiology, it is my firm belief that the chief factors are foul air and overexertion of the brain sufficient to bring about inflammatory processes. The first case I ever saw was unquestionably brought on by hard study in a small room in which the air was made still more foul by the burning of a kerosene-lamp. That case proved fatal."

Dr. E. S. Peck said: "I desire to pass around these two preparations of the temporal bone, one of which shows the cavity of the middle ear with the round and oval windows, the course of the chorda tympani and other tympanic nerves, the exceedingly thin roof of the tympanum, the near proximity of the lateral sinus and the osseous Eustachian tube; the other is opened so as to exhibit the aqueduct of the cochlea, the thin scale of bone over the aqueduct of the vestibule, the course of the superior petrosal groove, and the three semicircular canals. They are purely anatomical preparations, but they serve to explain the course of the aural complication of cerebro spinal meningitis by the aqueduct of the cochlea rather than by the middle ear.

"Among a number of bony preparations of aural disease in my possession, there are two specimens showing the involvement of the petrous bone due to cerebro-spinal fever. There is evidence in both these cases that the pus travelled along the acoustic nerve-sheath, and that exudations were present even in the labyrinth. The history of neither case conveys information as to whether there was pus in the middle ear, or even congestion of this portion of the auditory apparatus.

"I was fortunate enough to spend an afternoon with Von Tröltsch, in Würzburg, some years ago, when he showed me a large number of petrous bones, some of which were the results of autopsies in cases of cerebro-spinal fever. It was his opinion that the internal ear was the part of the auditory apparatus usually involved, by means of pus following along the acoustic nerve; and with this opinion the experiences of Luschka and Lucæ coincide. Von Tröltsch also states that some of the autopsies in cases of cerebro-spinal fever with deafness show pathological changes in the fourth ventricle of the brain. The distinguished author of the paper, in a valuable contribution on this subject published in The Medical Record, December, 1883, wrote of the frequency of a mild form of inflammation of the middle ear, with a return of hearing power. He also stated that suppuration of the middle ear may occur; and, further, that deafness occurs in one patient out of ten. With this opinion Roosa strongly concurs, and bases his conclusion on the fact that bone-conduction of sound remains to a limited extent, this being an indication of functional ability on the part of the acoustic nerve. I do not think, however, that autopsies will bear out this theory. A singular clinical fact in this connection is that facial paralysis rarely occurs as a complication. Its absence is used as an argument to prove the absence of inflammation of the acoustic nerve, with which it lies in close contact."

Dr. Smith asked Dr. Peck how he accounted for the fact that deafness is always bilateral.

Dr. Peck replied that it was due to the basilar tendency of the meningitis; that many cases of simple meningitis occurred with unilateral deafness or monocular amblyopia.

Dr. Peck, in reply to inquiries of Dr. Dana and Dr. Newman, further said that he had made ophthalmoscopic examinations of cases of chronic cerebro-spinal meningitis, and of simple meningitis, in which there was perioptic œdema, succeeding to infiltration of the optic sheath. Some of them had loss of central vision, total or partial, while in the equator of the eye the retina appeared normal. "Almost all cases of inflammatory œdema of the basal meninges are followed by *neuritis descendens* and *neuritis optica*. I am now treating a patient, sent by Dr. Leo, for the relic of an old meningeal œdema. The patient is a lad, seven and a half years of age, who, in infancy, had severe convulsions, evidently due to cerebral congestion. The child was sent on account of alarming beatings in the head and conjunctival trouble. The right eye could count fingers at two feet; the left eye had a vision of $\frac{2}{4}\frac{0}{0}$; there was no anomaly of refraction; both lower lids were slightly granular. Loss of vision was not suspected. The beatings could be traced along the superior longitudinal sinus, and over the parietal and temporal bones of the right side of the head. With the ophthalmoscope the right eye gives evidences of perioptic œdema, chiefly in the outer and inferior parts of the disk. There are, in addition, three dirty-white spots of good size around and very near the disk; they are spots of atrophic choroiditis, and are totally devoid of pigment deposits. Under the use of potassium bromide and ergot these beatings have disappeared; and in three months the right eye, with a previous vision of finger-counting at two feet, sees $\frac{2}{4}\frac{0}{0}$, and the left better than $\frac{2}{5}\frac{0}{0}$. I cannot believe that in all cases the ophthalmic involvement is peripheric, as shown in affections of the choroid, iris, and cornea, but often central, as in descending neuritis, optic neuritis, etc.

"I would like to add here that it must not be deduced from this that all infantile convulsions are manifestations of true meningitis."

Dr. A. R. Robinson said: "I think some of the cases cited to-night as cases of cerebro-spinal fever should be excluded. I do not think that there is any direct connection between syphilis and the special exciting agent of cerebro-spinal fever. The simple existence of micrococci alone is not regarded as sufficient proof of the bacterial origin of any disease. As regards cerebro-spinal fever and pneumonia, I have never noticed in the cases coming under my care any connection to exist between them. Three years ago I was called to see a child who had been vomiting, whose temperature was 102½°, and on whom these eruptions were present. The diagnosis was held in abeyance. The next day the child was, to all appearances, perfectly well, and I did not intend to go again. But on the next day I was informed that the child was not so well. I went to see it, and there was nothing to lead me to suppose that it was cerebro-spinal fever. On the fifth day the head was drawn back. I would like to know if that case was not an unusual one—the symptoms being so severe in the first twenty-four hours, and then the patient appearing to get well."

In closing the discussion, Dr. Smith said: "I think I can answer the question of the President. It is a remarkable fact, of which there is no satisfactory explanation, that patients occasionally present well-marked symp-

toms of the disease, such as intense headache and rigors, which entirely subside for some hours, perhaps for a whole day, and then recur, and the disease runs its usual course afterward. I have in mind a case seen some years ago in Thirty-fifth Street, where a young man had the disease so severely that he went into convulsions. But the convulsions did not occur the first day. The intense headache, however, came on with vomiting and fever. The next day he was so far relieved that he went to Brooklyn on business. On his return the symptoms reappeared with convulsions. This fact is stated by different writers as peculiar to this disease.

"In regard to its contagiousness, it has been said that in the epidemic form it is contagious, and in the endemic it is not. I do not believe that it is contagious at any time. If so, the degree is so slight that there is no need of isolating patients. In the epidemic of 1872 I saw perhaps over fifty patients. The great majority of them were single, isolated cases. There were some multiple cases—that is, in one instance, two in a family; in another, three; and in another, four; but in many of these cases the sanitary conditions were obviously very unfavorable. The four cases in one family occurred in Fifty-fifth Street, near the river. They carried on the business of making what is called head-cheese, and the heads of hundreds of cattle were there in a condition of decomposition.

"I have never seen any evidence of its contagiousness, and do not think that even in its most severe epidemic form there is any need of isolating those affected.

"As regards the diagnosis, I know that many cases do have hemiplegia on the second day. In the commencement of the severe form of the disease there is more or less congestion of the cerebral substance in connection with meningeal inflammation. In cases where there is any doubt, hemiplegia may occur a few days after the attack, and on that account some consider it a distinct disease from cerebro-spinal fever.

"I do not say that mistakes may not be made in the other direction—that many cases are called cerebro-spinal fever which are really not so. So far as my observation extends, we do not have full statistics of this disease.

"Cerebro-spinal fever is a disease *per se*; that is, it is due to a specific principle which is entirely distinct in its nature from any other disease. I simply stated what foreign observers have mentioned in regard to its occurring as a complication of pneumonia. I have met it occurring in connection with some other diseases, but not with croupous pneumonia; as, not long ago a case of entero-colitis, in which I expressed the opinion to the attending physician that in all probability the cerebro-spinal irritation had a reflex origin, but the physician afterward informed me that it was undoubtedly a case of cerebro-spinal meningitis, because the intestinal disease got well and the other disease continued."

Bad Breath.—Dr. Frank H. Gardiner believes that decaying particles in the mouth as far back as the pharynx vault taint the breath exhaled very little, if at all. Mouth-breathers have a bad breath when the tonsils are enlarged, or when cheesy masses exist in the tonsillary mucous folds. Certain gastric derangements taint the breath only when gases are eructated through the mouth. The principal cause of bad breath is decomposition in the intestinal canal, the retention of fecal matters in the transverse and descending colon, and the absorption of gases into the circulation, finally exhaled by the lungs. Catarrh (nasal, pharyngeal, laryngeal, or bronchial) causes bad breath. Medicines or aliments which undergo chemical changes below the œsophagus may, by rapid absorption through the stomach-walls, or immediately below, give to the breath the characteristic odor. This bad breath is often a source of serious annoyance to patients, and the fact that it has more than a local cause is too often ignored by the physician who, therefore, fails to cure it.—*Dental Review.*

OUR LONDON LETTER.

(From our Special Correspondent.)

PSORIASIS AND RHEUMATISM—INTUSSUSCEPTION CAUSED BY TUMORS—THE PRESIDENT OF THE COLLEGE OF PHYSICIANS—THE WHEELHOUSE AND FOSTER ELECTION EXPENSES FUND—THE PHARMACY BILL—THE LATE DR. BRADY—THE WIRE-TREATMENT OF THORACIC AND ABDOMINAL ANEURISMS—THE SOCIETY MEETINGS—THE BRITISH MEDICAL ASSOCIATION—EXCLUSIVENESS IN MEDICAL SOCIETIES.

London, April 12, 1887.

Psoriasis and its relations formed one of the topics discussed at the last meeting of the Clinical Society. Sir Dyce Duckworth read the notes of a case in which well-marked psoriasis was associated with rheumatism. Salicylate treatment was adopted, but it proved powerless to reduce the temperature or control the arthritic disease. Arsenical treatment was therefore substituted for it, and under this a steady improvement went on. Local treatment was also employed for the psoriasis. The latter gradually became transformed into diffuse exfoliative dermatitis (pityriasis rubra). Sir Dyce Duckworth observed that psoriasis was not uncommon in rheumatic persons, especially in those suffering from rheumatoid arthritis. Dr. Radcliffe Crocker remarked that his experience also pointed to the possibility of a connection between rheumatism and a previous dermatitis. Any form of dermatitis might be the antecedent. He also remarked that psoriasis was the most common antecedent of pityriasis rubra when the latter did not occur as the only disease. Dr. Barlow said he had also observed the triple association of psoriasis, pityriasis, and rheumatism. When once the skin-lesion had taken on the exfoliative type, this form would continue.

Mr. Arbuthnot Lane related a case of intussusception produced by the presence of a tumor growing from the mucous membrane of the transverse colon. The patient was a child, eight years of age. The tumor came down on two occasions and protruded from the anus. The second time it was removed, and on subsequent examination no signs of an intussusception could be made out. Mr. Treves said the mildest cases of intussusception were often those associated with large polypi in the colon. Polypi were present in five per cent. of the cases of intussusception. A mass of epithelioma in the wall of the bowel might also lead to the formation of an intussusception. Mr. Barker said he thought the latter was not a very frequent cause of intussusception. Mr. Bryant was of opinion that intussusception, caused by tumors were not very rare, but that in adults they were not recognized sufficiently. He believed a fair proportion of the cases in adults were due to tumors. In illustration, he narrated the case of a lady, eighty-four years of age, who had lately been under his care. The abdomen was tympanitic, and there was acute obstruction following on long-standing bowel-trouble. On examination per rectum a growth as large as an egg was detected. It was readily removed, and recovery ensued. The growth was of a coarse, villous nature.

At the Medical Society Sir Dyce Duckworth presented a case of ulcerative endocarditis simulating typhoid fever and acute tuberculosis. The patient was a girl, twenty years of age, in whom there was no history of rheumatic fever, but some of the joints were swollen. The necropsy revealed no tubercles or splenic infarctions, but the mitral valves were much diseased and fungating.

Mr. R. W. Parker read a paper on "The Alleged Dangers of Starch-containing Foods during the Period of Infancy." He thought these dangers had been greatly exaggerated. He was no advocate for artificial feeding, but he thought that too much stress had been laid upon its effects. He attributed more importance to the

hygienic surroundings. Mr. Parker said he thought that in many cases the mortality of artificially fed children was due to debilitating influences of various kinds acting on the parents before the birth of the children.

To the surprise of many, Sir William Jenner has been re-elected President of the College of Physicians for the seventh time. This is no doubt in consequence of the desire to carry through the new policy of the college of endeavoring to obtain powers to grant a degree in medicine. Sir William is a firm advocate of this scheme, and it is very doubtful whether any other man would be able to exercise the same influence. Sir Andrew Clark might, possibly, if Mr. Gladstone were in power. Sir William Gull is an able man, but has made many enemies. In connection with this election it is curious to observe that only one hundred and twenty fellows took part in it, of whom only seventy-three voted for Sir William Jenner at the first ballot. Neither members nor licentiates have a voice in this or in any other matter connected with the college. The presidency and all other offices are therefore in the hands of those few fellows who take an active part and settle many matters across each other's dining-tables.

The process of sending round the hat for the "Wheelhouse and Foster Election Expenses Fund" has not been attended with very happy results. No list of subscribers has been published, but as, with every effort that could be made, only some eighty pounds odd has been raised, it must be concluded either that the number of the admirers of these gentlemen whose admiration is sufficiently warm to unloose their purse-strings is very small, or that the greater number of those donating have reserved for this occasion the proverbial threepenny bit. As three hundred and thirty-eight pounds twelve shillings and twopence has been expended, Messrs. Wheelhouse and Foster have had, after all, to pay most of it themselves, and considering that the office to which they have been elected is a paid one, they can well afford to do it.

The Pharmacy Bill has passed the second reading in the House of Commons, and is likely soon to become law. It gives more power to the Pharmaceutical Society and authority to create a compulsory curriculum for pharmacists. Times are so changed that we can scarcely realize that it is but little more than a quarter of a century since anyone who chose could open a chemist's shop and sell poisons without let or hindrance.

A notable figure has just disappeared in the person of John Brady, F.R.C.S.I.—generally called by the public Dr. Brady. For twenty-seven years he was M.P. for Leitrim, on the Liberal side, but his genial and kindly disposition made him friendly with all parties. He was for years the only doctor in the House of Commons, and he was always ready to give his time and influence in the service of his professional brethren. One Act of Parliament was certainly entirely due to his efforts, and others he greatly assisted in passing. He practised in London for several years, on the south side of the Thames.

London, April 16, 1887.

The treatment of thoracic and abdominal aneurisms by the introduction of steel wire into the sac was discussed very fully at the last meeting of the Medical and Chirurgical Society, and the subject occupied the attention of the Society for the whole evening. Three cases were related in which this method of treatment had been adopted, but the record is not very encouraging, as all of them terminated fatally. In one of these, though, the operation did not apparently contribute to the fatal result. The first case was read by Dr. J. J. Pringle, and was that of a man, forty-six years of age, with an aneurism in the upper part of the abdominal aorta. He was admitted into the Middlesex Hospital, and general treatment was employed for a month. No benefit resulting, he was operated on by Mr. Henry Morris. It was not found possible to introduce more than a foot of the wire. No hemorrhage of consequence occurred, and the patient went on satisfactorily for two days. He then became almost maniacal, and died of asthenia in five days. At the necropsy both sides of the heart were found distended with mixed clot. The aneurism was also found filled with clot, more than a third of which was laminar, and presumably due to the introduction of the wire. The second case was one of sacculated aortic aneurism in a man forty-eight years of age. Iodide of potassium and a restricted diet having been tried for nearly two months without benefit, it was determined to operate on him. Mr. Pearce Gould operated on him in the Middlesex Hospital, and introduced thirty-two feet of steel wire through a Southey's cannula into the aneurism at the most prominent part of the swelling, viz., in the third interspace on the right side. A good deal of blood was lost at the time of the operation, and from one of the two punctures made a considerable quantity of reddish serum continued to drain for some days. On checking this by pressure, swelling of the subcutaneous tissue occurred, the skin became gangrenous, and death speedily ensued. At the necropsy the intra-thoracic portion of the aneurism was found to have a small but distinct sac springing from the first portion of the arch of the aorta, which was much dilated. The extra-thoracic portion of the aneurism, however, had no distinct sac, but was bounded by infiltrated muscle. A very dense mass (consisting of the wire and loose fibrinous clot) filled, but was not adherent to, the sac. The remaining case was also that of a patient at the Middlesex Hospital, but under the care of Mr. Hulke. The patient was a sailor, and the aneurism (subclavian) came on as the result of injuries received in falling from a height. After various treatments had been pursued at intervals for two years, the aneurism was a little smaller, but not otherwise much improved. The patient left the hospital, but returned in a month with increase of pain and swelling. Mr. Hulke operated, and introduced thirty-three feet of steel wire through a cannula. Some degree of hardness of the sac followed the operation, but no other change could be made out. Five days after the operation there was a good deal of pain and increased arterial tension. This was relieved by bleeding. On the thirteenth day from the operation the patient died. On examining the parts after death only a small amount of clot was found about the wire, and there was no appearance of inflammation. In the discussion on the three cases several speakers commented unfavorably on the great length of wire which was introduced. Mr. Bryant suggested that good fishing-gut would be preferable to steel wire. This opinion Mr. Morris seemed disposed to accept, but he remarked that he was not previously aware that fishing-gut could be made to coil up. Mr. Pearce Gould said he should not in future cases use anything approaching the quantity of wire used in his recent case. He agreed with Mr. Bryant that the evidence was against the employment of steel wire.

In the course of another month many of our medical societies will have suspended their labors for the season, only to resume them in October. By a sort of tacit convention nearly all the meetings of societies take place only during the winter months, and as they are nearly all held in the evening the temptation to quit a warm fireside is sometimes not very keen to doctors who have had a busy day. Taking both town and country into consideration the number of societies devoted to the medical sciences is very numerous. Almost every provincial city of any consequence has its own medical society, besides a local branch of the British Medical Association. The latter, indeed, is now almost co-equal with the distribution of the profession—in England, at any rate, though perhaps not in Scotland and Ireland. Its various branches, no doubt, fulfil many useful, social, and scientific purposes. As regards the parent association, its chief function is that of producing the weekly *Journal*, and it might fairly be described as "a co-operative journal-producing association." The importance attached to the *Journal* is evidenced by the fact that at the new offices

of the Association the inscription is *British Medical Journal.* The impression made upon an impartial observer naturally is that the Association is a mere appanage of the *Journal*, and that the sole use of its faithful members is to provide for the editor and his associates "the sinews of war" wherewith to carry it on. An organization so extensive is naturally not very exclusive. New members can be elected by the council of the Association, or by any branch council. In either case they must be nominated by three members of the Association, to *one* of whom they must be personally known. Under such conditions the term "member of the British Medical Association" really signifies little more than "subscriber to the *British Medical Journal.*" An association which is always seeking to extend its members cannot be very exclusive. Everything, in fact, is sacrificed to mere numbers. One of the younger of the medical societies in the metropolis—the British Gynecological—has fallen into the same error. When it was founded proposal forms were sent to all and sundry, inviting them to join, and a not very select body has been the result. As an inducement to country doctors to join, it is stated that "the Society holds meetings from time to time in the large towns of Great Britain and Ireland."

The Neurological and Dermatological Societies have been constituted on much narrower bases. The latter is, perhaps, the most exclusive medical society in the metropolis. Its number is limited to thirty. In the event of a vacancy occurring a candidate must be nominated by at least ten members, and one black ball excludes. Its meetings are devoted entirely to clinical work, viz., to the exhibition of cases, drawings, specimens, etc. They are not announced in the medical journals, nor are its proceedings reported. In this the Society but imitates the reserve of one of the oldest of the London societies—the Hunterian—which for many years conducted its meetings in strict secrecy and would allow no account of them to appear in the medical journals. This rigidity, however, has been relaxed of late years, and its members now frequently have the honor of seeing their sayings and doings recounted in print.

LARYNGOLOGICAL HERESY.

To the Editor of The Medical Record.

Sir: The pessimistic views advanced in the various articles relating to topical medication of the upper air-passages, published in The Medical Record of April 30th, contain, in the light of my own experience, so much heresy, and are, I think, calculated to do so much damage, that I cannot refrain from protesting. As an outcome of my own experience in private practice, I feel justified in asserting the following propositions:

1. That any practitioner who is not making a *successful* use of topical medication of the air-passages, from the nostrils down to the capillary bronchial tubes, is either behind the times in general knowledge, or is lacking in skill, or is not doing his whole duty by his patients.

2. That, although cure of chronic disease in these passages usually is dependent upon removal of causes, still most chronic cases need the help of topical medication to enable the tissues to overcome the bad habits of pathological action, which habits are likely to persist, without such outside help, even after the removal of the causes. Furthermore, that many chronic cases, without removal of causes, can be brought into practically normal states by such applications, and although having a tendency to relapse, can be retained in a normal condition by occasional applications.

3. That, although the bulk of such applications, as they are usually made, are of non-effect, absolutely harmful, or only alleviative, still, when *skilfully* made, can accomplish that which is really wonderful and which cannot be done in any other manner. Even such serious disorders as laryngeal phthisis and purulent bronchitis of many years' standing may be practically cured by the help of local medication, when constitutional and hygienic treatment by themselves have been unable to effect cure.

4. That, although the establishing of nasal respiration by the purely surgical methods is the most brilliantly satisfactory work we accomplish, still, nasal stenosis and irritation is not the sole cause of disorders of the pharyngeal vault, larynx, and trachea, but, on the contrary, has a causative influence small in comparison with climate, occupation, exposure, malnutrition, abuse of the stomach, and unhygienic habits.

5. That extreme laudation of chromic acid as a means of treating nasal hypertrophy, etc., is to be deplored, for the fact is, that of all known agents for effecting this purpose, it requires the most skill in its *safe* use. It is very easy to apply chromic acid in the nose, and it is very easy to inflict great damage by its use.

6. That instead of our *armamentarium* being uselessly large, we have need of its greater extension. Every case operated on differs in some respect from others; hence there is a field open for the continual production of instruments that shall be best fitted for each particular class of cases. It is true that there is need of greater visible simplicity in the fittings of our operating-rooms, for the exhibition of a large amount of complicated machinery is terrifying to the average patient. The ideal equipment should comprise a large, inexhaustible cautery battery, some reliable mechanical motor for drilling, powerful pumps and large reservoirs for compressed air for the extended production of sprays, especially of the nebulized sprays, means for the production of hot vapors and the convenient taking of fuming inhalations, as well as for administering air of varying processes and of medicinal gases. Such an equipment is quite complicated and bulky, and as most of it should be out of sight of the patient, it is apparent that there is an inventive field still open. The utility of all these mechanical means can be affirmed by others, as well as by the writer. In the not distant future, a chest clinic will not be considered well equipped without a complete apparatus for the topical application of remedies. The benefit that may be conferred by the topical treatment of the coincident bronchitis of phthisis is of itself sufficient to rank medication, by the inhalation of nebulized remedies, as one of the most valued practical procedures of medical therapeutics.

7. But the production of best results through topical medication of the air-passages does require *special* knowledge and skill, which can only be gained by experience on the part of those having natural adaptability. The art, so far as I know, in its refinement, is *not* taught in the books nor in the schools. Nevertheless there are many professional brethren who can, out of their individual experience, substantiate the propositions here made. In a general way, if I can judge from observation of the practice of the unsuccessful topical applicators, in comparison with those who are successful, those who fail err in judgment as to selecting the best means for fulfilling the indications presented, are too harsh in the treatment, use too strong remedies, stimulate too much, soothe too little, do not take sufficient time in making applications, nor make them with sufficient frequency. It is my habit to charge many of my patients a contract price, rather than to charge so much per visit, so as to encourage them to make as many visits as may be desirable. The curative treatment of most dispensary patients by the means now at command is practically impossible. The necessary time could not be given to the patient even if proper equipment and skill should be available. There is then some reason for the sneering remarks frequently made relating to the "specialists and their astringents." But when, without the anæsthetic aid of cocaine, a subacute nasal catarrh can be cured at one sitting; when post-nasal catarrh caused by habitual gormandizing, or by the congestive action consequent upon heart lesions, can be controlled by quite infrequent applications; when a painful sore-throat can be absolutely cured in five min-

utes; when a husky-voiced singer can at one sitting be put into condition to sing splendidly all day; when the destructive ravages of laryngeal phthisis can be stopped, the parts healed, in some cases the voice partially restored, and the patient restored to a partially useful life; when very great comfort, and in many cases curative aid can be extended to cases of pulmonary phthisis; when "colds" that would ordinarily run for two or three weeks can be instantly alleviated and cured within three days; when patients can be helped to reside in health and comfort in localities, the climatic disadvantages of which would be otherwise insurmountable; when all these optimistic facts, and others that could be named, as resulting from the skilful use of the present methods of local treatment of the air-passages are considered, I submit that the general tenor of the articles referred to in the beginning of this communication is an unjust disparagement of the art of laryngology as it now exists in its best forms.

J. M. W. KITCHEN, M.D.

168 WEST FIFTY-EIGHTH STREET.

SHOULD DOCTORS FURNISH MEDICINES?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I beg to be allowed space to "second the motion" contained in Dr. McManus' communication in THE RECORD of the 9th inst., "Should Doctors furnish Medicines?" It is a timely and wise hint. The evil of counter-prescribing by druggists, to which he calls attention, is a growing one, and the exceptions to the rule of competent and honest druggists who attend to their own legitimate business, strictly limiting themselves to its proper bounds, are getting to be more numerous. Out of this evil have sprung nearly, if not quite, all the complaints of physicians in recent times against druggists; the nuisances of travelling salesmen, sample packages, and bogus journalism, or proprietary-medicine certificates and pamphleteering. If physicians would become skilled in the preparation of their remedies, many a doctor will not only acquire "a familiarity with drugs, which was, perhaps, sadly needed," as Dr. McManus suggests; but will do much to correct the evils of which physicians have so much now to complain. It will encourage legitimate pharmacy and tend to drive out of its ranks the class of druggists who deal in the cheaper and inferior sorts of drugs and proprietary preparations, and with them the manufacturers of them. We would be far from bringing about any antagonism between ourselves and patients on the one side, and honest and competent pharmacists on the other. We need their services and their hearty good-will and co-operation, and right well has the *science* of pharmacy in our times shown itself the handmaiden and servant of the medical profession in the elegant and efficient fluid extracts, properly prepared tinctures and pills, etc., so easy of carriage and dispensing by the physician. With such means it is easy enough for physicians to establish a suitable and proper independence in the matter of furnishing medicines for their patients.

There is no need, however, of *supplanting* the druggist's business. It is only the capacity of becoming his own druggist for such emergencies as may arise from time to time, to be able to secure the best remedies in his practice, and to prevent improper interference on the part of such druggists with his written prescriptions as need it, which the physician needs.

With such a knowledge as all physicians should have of the materia medica and of the drug market, there could be no difficulty on the part of physicians in having druggists fill their prescriptions with the best and purest medicines, or failing in this, to do it themselves.

In regard to the sources of supply it can be truly said that it requires some patience and care in making proper discrimination among the various pharmaceutical manufactories. If physicians are not hopeless gudgeons in this matter (and they need not be), by shunning the drumming and advertising humbug and nuisance, and by a little patient inquiry and observation at the large centres of medical supplies, they will readily find out whose fluid extracts assay nearest to the claims set forth, and are of most uniform strength, and whose entire list of drugs and officinal preparations are most correctly prepared, and nearest to the officinal standard of purity and uniformity.

There is no need that "every physician should be his own druggist" at all times and always, any more than that every lady-housekeeper should do her own cooking and housekeeping, etc. The lady-housekeeper should thoroughly understand these things, however, to supervise her servants, and to do it herself when emergencies may arise requiring it; and by actual practice only can these arts be mastered. There is no intention to cast any slur on the highly developed science of modern pharmacy and scientific pharmacists by contrasting them with a menial order of work and servants. The contrast is used simply as the best illustration at hand to set forth the proper relation of physicians to their medical supplies and to pharmacists.

Very truly yours,

POCKET-CASE.

APRIL 13, 1887.

THE BEST TESTS FOR ALBUMIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your report in to-day's issue of the discussion of my paper, "The best Tests for Albumin," it is stated that I said: "Heat was the most available of all tests, doubtless, if all precautions were observed." This is incorrectly reported, and is so entirely at variance with my belief and experience, as well as with the opinion expressed in my paper to the effect that heat is "one of the most cumbrous of the important tests" (see p. 486), that I beg to correct it.

I will avail myself of the opportunity of saying that I am confident that a trial of the nitric-magnesian test will abundantly compensate anyone for the slight labor of preparing it. Thus far I have found no test cover so much ground.

Respectfully yours,

HENRY B. MILLARD, M.D.

NEW YORK, April 30, 1887.

LOCAL TREATMENT IN DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a communication in THE MEDICAL RECORD of this date, from Dr. J. Lewis Smith, the following sentences occur: In speaking of "treating the nostrils" Dr. Smith says, "I have used various syringes with tapering and bulbous nozzles, and Delano's hand-atomizer as employed by Dr. Billington. The objection to the latter is that the sharp point is very apt to prick the nostril and cause bleeding if the child resist and rotate the head." It is impossible that this should be true, for the reason that neither the Delano nor any other atomizer has ever been "employed by Dr. Billington" in the treatment of the nares in diphtheria, and such use of it has been mentioned by him only to be deprecated. As this has so lately been twice done by me in THE MEDICAL RECORD, it is with mortification that I am compelled to ask further space for this correction. Not doubting that this misrepresentation, though so extreme, was quite unintentional on the part of Dr. Smith, I shall only, by way of pointing a moral, crave his indulgence for the inaccuracies of the average "reporter" to which he alluded.

Yours truly,

C. E. BILLINGTON, M.D.

NEW YORK, April 30, 1887.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 1 to May 7, 1887.

FRYER, BLENCOWE E., Major and Surgeon. Ordered for examination by Army Retiring Board at San Francisco, Cal. S. O. 101, A. G. O., May 2, 1887.

STERNBERG, GEORGE M., Major and Surgeon. Assigned by the President to the special duty, under the Treasury Department, of "investigating the merits of the method practised in Mexico and Brazil for preventing yellow fever by inoculation." Relieved from duty as Attending Surgeon and Examiner of Recruits in Baltimore, Md. S. O. 101, A. G. O., May 2, 1887.

BILLINGS, JOHN S., Major and Surgeon. Granted leave of absence for ten days, to take effect May 3, 1887. S. O. 98, A. G. O., April 28, 1887.

MIDDLETON, J. V. D., Major and Surgeon; HAPPERSET, J. C. G., Major and Surgeon; AINSWORTH, F. C., Captain and Assistant Surgeon. Appointed to assemble at U. S. Military Academy, West Point, N. Y., on June 1st, to examine into the physical qualifications of the members of the graduating class and of the candidates for admission to the Academy. S. O. 102, A. G. O., May 3, 1887.

LORING, LEONARD Y., Captain and Assistant Surgeon. Sick leave of absence still further extended six months, on surgeon's certificate of disability. S. O. 103, A. G. O., May 4, 1887.

BIART, VICTOR, Captain and Assistant Surgeon. Sick leave still further extended one year on surgeon's certificate of disability. S. O. 99, A. G. O., April 29, 1887.

EWING, CHARLES B., First Lieutenant and Assistant Surgeon. Ordered from Fort Leavenworth, Kan., to Fort Lewis, Col., for temporary duty. S. O. 100, A. G. O., April 30, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 7, 1887.

SHAFER, JOSEPH, Assistant Surgeon. Detached from the Minnesota, and ordered to the Ossipe.

SIMON, W. J., Surgeon. Ordered to the U. S. Steamer Boston.

HENRY, C. P., Assistant Surgeon. Detached from Hospital, Philadelphia, and ordered to the Boston.

MEANS, VICTOR C. B., Assistant Surgeon. Detached from Hospital, Mare Island, and ordered to the Hospital, New York.

SIMONS, MANLY H., Passed Assistant Surgeon. Detached from Naval Academy, and ordered to the Constellation.

DIEHL, OLIVER, Passed Assistant Surgeon. Detached from Hospital, New York, and ordered to the Hospital at Philadelphia.

CHLORAL ERUPTION.—Dr. Barbillion has described a variety of erythema appearing in patients under the influence of chloral, upon the administration of alcohol. The chloral eruption was first recognized by Jastrowitz in 1869, and has since been met with by numerous observers. The point to which Dr. Barbillion calls attention is the almost mathematical regularity with which the exanthem appears under certain circumstances. Given a child of from four to eight years of age, who is taking from one-half to one drachm of chloral daily in repeated small doses, the administration of alcohol in the form of wine or spirit mixture will cause the appearance of the rash in from fifteen to thirty minutes.—*The Lancet.*

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 7, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	1
Scarlet fever	48	11
Cerebro-spinal meningitis	12	9
Measles	85	5
Diphtheria	78	44
Small-pox	30	7
Yellow fever	0	0

"INSTANTANEOUS" REMEDY FOR LUMBAGO.—Professor Burggraeve, Germany, recommends the following: ℞. Collodion, tincture of iodine, liquid ammonia, equal parts. M.—Sig.: Apply widely over the parts with a camel's-hair brush.

ARTIFICIAL HUNYADI JANOS WATER FOR CONSTIPATION.—℞. Magnesii sulphatis, sodii sulphatis, āā ℥ ss.; potassii sulphatis, gr. ij.; sodii bicarbonatis, gr. viij.; sodii chloridi, gr. xx.; aquæ ad ℥ viij. M.—Sig.: Wineglass before breakfast.

FORMULA FOR RHEUMATISM (St. Luke's Hospital).—℞. Potassii iodidi, ʒ iij.; vini colchici seminis, ℥ ij.; tincturæ opii camphoratæ, ℥ ij.; tincturæ stramonii, ʒ vj.; tincturæ cimicifugæ, ℥ iij. M.—Sig.: Teaspoonful three or four times a day.

SOOTHING MIXTURE FOR CONSUMPTIVES.—Dr. J. B. Johnson, of Washington, writes to the *Medical and Surgical Reporter*: "Of all the mixtures for stimulating the consumptive patient, allaying his cough, and quieting his nervousness, I have found none equal to the following: ℞. Syrup liquorice root, ℥ j.; aromatic syrup rhubarb, ℥ ss.; fluid extract of opium, ʒ j.; liquor ammon. acetat., ℥ v. M.—Sig.: Shake well. Dose: A tablespoonful every two or three hours. Patients become very fond of this mixture, and it in nowise interferes with the stomach or appetite. Should constipation ensue, it is easily overcome by an occasional dose of comp. liquorice powder.

INEQUALITY OF PUPILS IN HEALTHY PERSONS.—From an examination of one hundred and thirty-four healthy recruits, Dr. G. S. Ivonoff, of Kïrïlov, came (*Vratch*, No. vii., 1887, p. 162) to the following conclusions: 1. Equal or symmetrical pupils, as well as equal or symmetrical halves of the face, are met with but very seldom, the former only in nine per cent. of the persons examined, and the latter only in 2.2 per cent. 2. The inequality or asymmetry is probably dependent upon an asymmetrical development of the cerebral hemisphere. 3. In 54.5 per cent. of persons, the left pupil, and in 73.9 per cent. the left side of the face, is larger than the right one.

FATAL POISONING FOLLOWING TWO VAGINAL DOUCHES WITH CORROSIVE SUBLIMATE SOLUTION.—Fleischmann, of Prague, has reported the following case (*Therapeutic Gazette*): A perfectly healthy primipara, aged seventeen, exhibited no symptom of kidney disease or of any other complication of pregnancy. To disinfect the vagina before labor two douches of 1 to 2,000 solution of sublimate were given, one before and one after examination by a midwife. It was noticed that a small amount of bloody mucus was expelled from the vagina after the douches. In a few hours abdominal pain, diarrhœa, and a rise of temperature occurred, all the symptoms and lesions of mercurial poisoning developed, nephritis, salivation, and continued diarrhœa, and, after giving birth to a living child, the patient died in coma on the ninth day after

the douches were given. The pathological anatomical diagnosis made at the autopsy was "corrosive sublimate intoxication, acute nephritis, dysentery, stomatitis and pharyngitis in the stage of ulceration, parenchymatous degeneration of heart and liver, lobar and lobular pneumonia, bilateral acute cystitis." On investigation it was found that after receiving the douche the patient had left her bed and gone about her work in the ward. It is not probable that any considerable amount of fluid remained in the vagina after the douche, as all ordinary precautions were taken to secure its expulsion. It is, however, quite possible that some of the fluid may have gone into the uterus and become absorbed by any superficial lesions which had occurred in the beginning dilatation of the os uteri. It was also true that the patient had diarrhœa before the douches were given, and in his remarks upon the case Fleischmann calls attention to the danger attending the use of sublimate in puerperal patients in whom any lesion or disordered condition of the kidneys or bowels exists. He quotes the words of a well-known obstetrician, who asserts that the use of sublimate should be limited to the disinfection of the external genitalia and hands and instruments.

Drugs which Increase and Drugs which Decrease the Secretion of Milk.—Giurleo calls attention to the peculiar properties of *Ditana digitifolia*, which, he claims, possesses the power to stimulate the secretion of the mammary glands. The author found an opportunity to try the remedy on a number of wet-nurses, and pronounces himself as extraordinarily satisfied with the results obtained. In some instances, in which the secretion was almost wholly absent, the ingestion of an infusion of the plant produced a copious supply of milk. In Italy an ethereal tincture of *Ditana digitifolia*, combined with syrup, has been known for a long while under the name of "galatiofore." The blossoms and buds of the plant, besides, possess diaphoretic properties. The same author asserts that *Rhamus alaternus* and *Ligustrum vulgare* have properties precisely opposite to those of *Ditana digitifolia*—*i.e.*, they decrease the secretion of milk. The author uses an infusion of these plants (forty-five grains of the leaves to six ounces of water), and orders for several days this quantity of the infusion to be used up twice a day.—*Therapeutic Gazette.*

Bright's Disease.—Professor Dieulafoy says, in relation to Bright's disease, that the nice points that authors try to make as to the particular form of lesion that exists in any given case will all fail you generally at the bedside. That, in fact, all the different lesions are often found in the same kidney, and as to which one predominates is a point that can only be determined with certainty by a post-mortem examination. His treatment all resolved itself into a milk diet and blood-letting. He insists on blood-letting whenever the patient presents any symptoms that portend uræmic convulsions. Professor Jaccoud's treatment is the same, in addition to which he is now using the inhalation of oxygen gas. He says that the number of casts or the amount of albumen in a given case he considers of less importance in a prognostic point of view than the specific gravity of the urine.—*Paris Correspondent of the Chicago Medical Journal.*

Peptone Suppositories.—Sauter prepares these suppositories with cacao butter, each containing twenty-five grains of peptone; they are mixed, and kept cold to prevent the fat from becoming rancid. In cases where patients cannot be nourished in the normal manner, they serve an excellent purpose, fifteen grains of dried peptone equalling two and one-half drachms of meat in nutritive value. Children may be given one suppository four times daily; grown persons, two or three times daily. The suppository should be lubricated with olive-oil, and the rectum previously cleansed by an enema.—*Therapeutic Gazette.*

Salol.—Dr. Kleefeld (*Berliner klin. Wochenschr.*, No. iv., 1887) gives the following report on the action of salol, a substance composed of sixty per cent. salicylic acid and forty per cent. carbolic acid: "The composition of salol induced me to give it a full trial in the town hospital (Goerlitz) during the last month, and the very satisfactory results compel me to bring it before the notice of the profession. According to our experience of salol in thirty-five cases (in which a thousand separate doses were administered) it has, like sodium, salicylate and antipyrin, a specific influence in rheumatic polythritis, but is preferable to them for the following reasons: 1. No untoward symptoms, such as collapse, arvomiting, etc., follow its use. Singing in the ears is rarely complained of, and is never severe. 2. The drug has no taste or smell, and is pleasanter to take than either of those just mentioned. 3. Its cost is low, the wholesale price in Germany being 30 marks per kilo.—30s. for 2½ lbs. The full dose, beyond which we have never found it necessary to go, is two grammes (half a drachm) three times a day, but half this amount has often been sufficient. Finally, I am of opinion that salol is a very acceptable addition to our materia medica." Dr. Georgi, Dr. Kleefeld's assistant, will shortly publish details of the cases thus treated.—*British Medical Journal.*

Piperonal.—Piperonal is the aldehyde of piperonilic acid, which is obtained from the oxidation of piperine. It crystallizes in small, colorless prisms. Its odor is that of vanilla; its flavor like that of menthol, but more lasting. It is insoluble in cold water, but soluble in alcohol and ether. Dr. Riccardo Frignoni first discovered its remarkable antipyretic properties. It is given in doses of 75 ctgr. every two or three hours. When given in larger doses it causes nausea and eructations, but produces no more serious results. It is principally valuable as an antiseptic.

Time is Money.—Patient (to young doctor): Why do you charge me so much, doctor? I had a similar trouble last year, and Dr. Pellet cured me for half this amount. Young Doctor: How long did it take him to cure you? Patient: Three days. Young Doctor: Well I've been working on your case for nearly two weeks. You can't expect to get two weeks' work for a three-day price.

Paris Hospital Therapeutics.—It may be useful to give, in a short way, as complete as possible, the kind of medicinal treatment employed in the hospitals, and we take the service of Professor Germain Sée as a guide. The following is from the official book of the Salle (or Ward) St. Jeanne, Hôtel-Dieu:

Diagnosis.	Treatment.
Anæmia	Hæmoglobine and pepsin.
Chlorosis	Sodii arsenias.
Zona	Antipyrine, 4 gm.
Hemiplegia	Todd's potion.
Peri-uterine phlegmon	Injections, terpine, nux vomica, and gentian.
Syphilis, cerebral	Biniodide of mercury, sulphur-baths.
Chlorosis	Ferri et potassii tart., sulphate of aconitine.
Albuminuria	Tannin pill, ergotin pill, terpine pill.
Mitral insufficiency	Sparteine sulph., convallaramin.
Pericarditis and aortic ret	Iodide of potass., digital., sparteine.
Myocarditis	Caffeine, sparteine.
Thoracic varix	Tinct. hamamelis, antipyrine, Vichy water.
Typhoid fever	Charcoal powder, naphthaline, quinine sulph., rectal injections.
Amyothropsia	Pill opium, mercurial frictions.
Mitral insufficiency	Digitalis infusion.
Dyspepsia	Charcoal powder, benzoate of soda, terpine.
Diabetes	M. Sée's régime, arsenic.
Hydroarthrosis	Antipyrine.
Phthisis	Arsenic, pill opium.
Dilatation stomach	Ipecac powder (5 ctgr.), cocaine hydrochl. (5 ctgr.); suppress all vegetables.
Not made	Jalap.
Emphysema	Terpine, iodide of potassium, pill opium, sparteine sulphate.

NAPHTHOL.

SOME OBSERVATIONS UPON ITS USE IN DISEASES OF THE SKIN.[1]

BY CHARLES W. ALLEN, M.D.,

SURGEON TO CHARITY HOSPITAL; ATTENDING PHYSICIAN NORTHWESTERN DISPENSARY, DEPARTMENT OF SKIN DISEASES; ATTENDING SURGEON TO THE BELLEVUE HOSPITAL, OUT-DOOR RELIEF, DEPARTMENT OF GENITO-URINARY DISEASES.

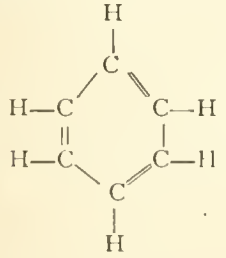
BEFORE entering upon a consideration of the therapeutic value of this comparatively new remedy, let us direct our attention for a few moments to the study of its chemical nature and the arguments to be drawn from this standpoint why it should be a drug of value to the physician. New remedies are being forced upon the profession faster than their names even can be committed to memory, and it is not to be wondered at that the busy practitioner, as a rule, practically and justly, too, ignores many of these new drugs, until those whose work and opportunities favor experimentation and investigation have determined their just value and separated those of real efficacy from the worthless. I believe the good book admonishes us to "prove all things, hold fast that which is good," but the man who hastens to carry out this precept by trying upon his private patients every new remedy proposed, will frequently find cause for regret, and his patients will often find it to their advantage to seek advice elsewhere.

I presume, therefore, that there are present to-night some who have had but little experience with naphthol, and that it will not be amiss to consider it from a chemical as well as a clinical basis, in order to appreciate better its *raison d'être*, and why, theoretically, it should be as useful as experience proves it *to* be. To premise, then, naphthol is a product of coal-tar. Now, this does not imply that the substance is found, as such, in coal-tar, but that it is produced indirectly from a substance which is so found. The substance from which it is directly obtained is naphthaline, a prominent constituent of coal-tar.

In the same way thousands of other bodies known in medicine, science, and art are produced, and are all known as coal-tar products.

Now, coal-tar itself, as is well known, is composed of a series of similarly or rather symmetrically constituted bodies. The most simple of these bodies is known as benzol, having for a formula C_6H_6, the molecule of which is graphically represented by a hexagon, thus:

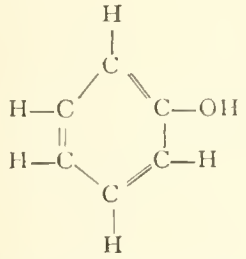
Benzol.—



This is known as the benzol nucleus, upon which other bodies are built.

Of this body there are several variations found in tar, in which one or more of the hydrogen atoms are replaced by other radicals. One of the most important of these is phenol or carbolic acid, the same being a benzol molecule in which one hydrogen atom has been substituted by an oxhydrogen radical thus:

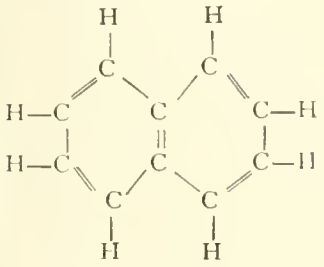
Phenol.—



Giving a formula C_6H_5OH.

Now naphthaline is very similar to benzol in its chemical constitution, being simply a double molecule of the latter.

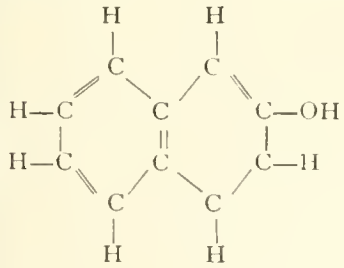
Naphthaline.—



Giving the formula $C_{10}H_8$.

Now, in the same way that phenol is derived from benzol, we find that naphthol is derived from naphthaline, and by substituting again in this double molecule an oxhydrogen radical for a hydrogen atom, we have

Naphthol.—



Giving the formula $C_{10}H_7OH$.

Naphthol is known commercially as alpha-, beta-, and hydro-naphthol. The distinction between the first two is due to the different positions of the OH radical in the molecule. The constitution of hydro-naphthol is not definitely known, but it is claimed by some to be synonymous with beta-naphthol. There is probably very little difference in the therapeutic action of these two products.

Beta- or hydro-naphthol is, then, the drug, now employed for external application, of which we speak.

It is a solid body, slightly soluble in water, having a peculiar odor, which, however, is not a very strong nor disagreeable one. It occurs in grayish-colored scales, or when redistilled as white, yellowish, or pinkish-white, large, leaf-like scales. I pass for inspection several varieties of beta- and hydro-naphthol, now to be had in New York. The imported article, prepared by Merck, in the first bottle I pass, is that which I first employed and

[1] Paper read before the Manhattan Medical and Surgical Society, April 2, 1887.

with which I have had the most experience. It has a stronger, more pungent odor than the others, and a strong whiff of it will probably cause sneezing. The second specimen resembles it in color but is more finely divided, the scales being more powder-like and the odor is much less pronounced. This is the preparation put upon the market under the name of hydro-naphthol.

The third specimen is a purified naphthol almost devoid of odor. As you see, the scales are large and flaky, and present a beautiful appearance. The next specimen is one of alpha-naphthol, which I am sorry to say is to be found upon some dispensing shelves. The reddish crystalline mass in the next bottle is an example of the impure drug, still sold and dispensed in some public institutions, if not in private shops.

Hydro-naphthol makes a darker solution in alcohol or ether than the others, but clinically it has given equally good results in my hands so far as I have employed it. Naphthol is soluble in alcohol, ether, the fixed oils, but only very slightly soluble in water. It can therefore be employed in almost any manner desirable. I have used it mostly as an ointment or collodion dressing, but have also at times employed solutions in alcohol and oil. I show you a solution of the drug in flexible collodion which I have had prepared, and you see it makes a clear brown-colored paint. I have been much pleased with this fixed dressing, and have found it of value in psoriasis, eczema, syphilitic ulcers, and a variety of other conditions

I also show you some naphthol soaps, of five per cent. strength, which are now obtainable in the shops, and which appear to me to be useful in many affections in which baths are indicated, and they can be used in conjunction with ointments or other preparations.

Unna, of Hamburg, has included among his salve and plaster muslins one of naphthol. This I have not used as yet, but theoretically it should prove an excellent application. Just now these muslins are not to be had in this city, the leading drug houses will have a supply within a short time.

I have requested some well-known manufacturers to make me some naphthol plasters, and I hope to report upon their use at a subsequent meeting.

Tar has ever been one of the most highly prized substances for external employment in diseases of the human integument. In eczema, in psoriasis, in the parasitic diseases, and in all conditions attended with pruritus some preparation, made with one or the other forms of tar has often been found to give relief and speedily prove curative. Until chrysarobin was introduced for the cure of psoriatic lesions, tar was the great remedy for this disease. Now tar, as known in therapeutics, is a product of the destructive distillation of wood of various kinds, giving, according to the variety employed for the process, the ordinary pix liquida, or that known as pix burgundica, canadensis, or one of the derivative tarry oils, such as oil of cade (oleum cadini), oil of white birch (oleum Rusci), oleum fagi (beech), etc. Now, in hospital practice the application of tar and tarry preparations does well enough, but in practice in private families it will not do. Again, children and those possessed of delicate integuments will not tolerate its application. There are, furthermore, individuals who show a decided idiosyncrasy as regards tar, and at its first application suffer from inflammation, redness, burning heat, and intolerable itching in the parts to which it has been applied. For these reasons, and because of its, to many, objectionable odor and staining properties, and the fact that it occasionally produces toxic symptoms, it becomes an unavailable drug in many cases, although its virtues may be well recognized.

This well-known therapeutic value of tar is explained by a study of the constituent parts of coal tar in a measure, for all tars are quite similar, chemically. The presence, however, of a large amount of benzol (one to two per cent.) in coal tar makes this less desirable than the wood tars as a therapeutic agent; besides there is an absence of all balsams and ethers, which are peculiar to the wood tar and make it valuable.

Now, although coal tar is not, in its crude state, applicable to skin therapeutics, the presence of very large quantities of carbolic acid, naphthaline, and other more complex multiplications of the benzol nucleus has made it indirectly of vast importance in medicine.

When coal tar is distilled, the most volatile products, such as benzol, toluol, etc., come away first, and under a greater heat crude carbolic acid comes over.

Carbolic acid was first discovered some forty years ago, by Calvert, and some twenty years later became recognized as a valuable disinfectant. In course of time its value in skin diseases was recognized, but it never supplanted tar, although in many respects it has served a useful purpose. The knowledge of its antiseptic properties has lately led chemists to believe that, owing to the similar chemical construction of benzol and naphthaline, if the derivative of the former possessed such marked properties, the derivative of the latter should prove of equal value. Naphthol has therefore been elaborated, and for a number of years has been subjected to trials and experiments to prove its value. Kaposi first recommended it as an application in dermatology in 1881, and in the *Wiener Medic. Wochen.* of July 29, 1882, gives a tabular statement of the cases treated at his clinic from April, 1881, to the end of March, 1882.

The cases aggregate 710, 454 of them being cases of scabies.

He regarded naphthol as one of the essentially curative ingredients of tar, and used it as a substitute for the latter.

His observations led him at this time to regard naphthol as a very active remedy, and one never to be employed without due caution. He found it of greatest benefit in scabies, a single application in many cases being sufficient to effect a cure. He used in this disease the following formula:

℞. Axung	100 parts.
Saponis viridis	50 "
Naphthol	15 "
Cret. alb. pulv.	10 "

After being briskly rubbed in, the patient is powdered with starch and wrapped in flannel blankets.

In prurigo naphthol is highly praised, and it gave good results in ichthyosis and eczema. Engelsted, physician-in-chief to the department of cutaneous and venereal diseases in the Copenhagen city hospital, reported, upon his use of naphthol in 1881, that he found it less reliable than linimentum styracis (bals. styracis liq., 200; ol. oliv., alc., āā 50), linimentum Hebræ, or preparations of tar in general.

He regards a solution (fifteen per cent. in alcohol and water) of naphthol as of great value in psoriasis, but not so sure and prompt as an ointment of chrysarobin. For itching diseases he recommended a one-half per cent. solution in alcohol and water (*Hospitals-Tidende*, 1882). Dr. Paul Sombret ("Thèse de Paris," 1883) speaks favorably of the drug in parasitic diseases and their concomitant eruptions, but found it of no value in psoriasis, and although the pruritus of Hebra's prurigo is rapidly dispelled by it, the curative action was found to be no greater than that of other well-known medicaments.

Dr. Van Harlingen read a paper upon the use of naphthol in skin diseases before the American Dermatological Society, August, 1883, in which he reported that he had found it of great service in scabies, and also of some value in psoriasis. In seborrhœa of the scalp he regarded it as a decided addition to our means of treatment. In his hands, however, it had failed to give relief in hyperidrosis, in which troublesome complaint Kaposi had found it useful. In ringworm its effects, he says, are inferior to almost all of the remedies at present used, and in most cases of tinea versicolor it is almost entirely inefficient.

In pediculosis, up to that time, he had had no personal

experience. In eczema it had failed to give the same beneficial results obtained by Kaposi. He was inclined to predict for it a not unimportant place in dermic therapeutics. Dr. Shoemaker read a paper upon the medical use and value of naphthol before the Philadelphia County Medical Society, October 17, 1883 (*Boston Med. and Surg. Journal*, October, 1883). He had found naphthol of benefit in the treatment of oily conditions of the skin, and that in scabies it fully maintained the claim that Kaposi had made for it. He found it also acted well in psoriasis and chromophytosis, as well as in some of the chronic forms of eczema, lessening infiltration, and especially in squamous and fissured forms of eczema. In fetid exhalations from the feet, bromidrosis, etc., Shoemaker recommends naphthol mixed with talcum, and dusted into the shoes and stockings.

Closely allied substances used in the therapy of the skin are carbolic, benzoic, salicylic, chrysophanic, and pyrogallic acids, many of which have a marked beneficial influence on those diseases in which tar was formerly found to act well. I do not propose to claim for naphthol that it will displace any of these named substances, but that it is in many respects preferable to tar and carbolic acid. At the present day it is an indisputable fact that no drug removes the eruption of psoriasis with the same certainty and celerity as chrysarobin. Pyrogallol acts well in many cases of this disease, as I have found by repeated trials, and has the advantage over chrysarobin of not producing irritation of the surrounding skin and discoloring both skin and clothing. I have notes of several cases of psoriasis in which the application of naphthol collodion has greatly benefited the patient, removing the scales and decreasing the thickened patches after a few applications.

Naphthaline is a substance which has been known to chemistry for some time, but has only recently found a practical application in medicine. It exists as such in coal tar, and is obtained from it by distillation at a high temperature, and occurs as white, glistening crystals. It has an aromatic odor and a burning taste, is soluble in hot alcohol, ether, and benzine, but not in water.

Besides having been recommended and, indeed, quite largely used internally in various intestinal disorders, it has had somewhat of a reputation as a dressing for wounds. When used for this purpose naphthaline should be purified by redistillation. It is said that naphthaline crystals can be better powdered by the addition of boracic acid. It is said to excite granulation in ulcers when applied in the strength of one to four each of alcohol and ether. Naphthaline, when applied to the skin continuously in strong solution, has sometimes been followed by irritation of the urinary passages, and even hæmaturia.

Dr. Lindenbaum (*St. Petersburg Med. Wochensch.*, June 2, 1883) recommends applications of naphthaline in frost-bite, and it has also been praised as a local application in erysipelas.

I show you a specimen of this substance, which was sent to me by a druggist upon an order for naphthol, and I wish to warn you against this error, which may lead you to attribute ill success to the drug when this error is the cause of your failure to secure the results expected. Naphthaline undoubtedly is an excellent drug, but it is not the same thing as naphthol, and does not give the same results, and there is no excuse for its being furnished when naphthol is ordered. My own experience with naphthol has extended over five years, but I have employed it more extensively during the past year than formerly. Indeed, the greater part of the two hundred and eighty cases of which I have record and now report, have been treated during this time, and many of them during the past six months. Some, on which treatment has but recently been commenced, I have not included, and in the neighborhood of one hundred cases of scabies treated in an institution I have also omitted. In these, partly because the nursing facilities could not be thoroughly carried out, and partly, as I now suspect, because naphthaline was being furnished instead of naphthol, as ordered, many of the cases did not improve rapidly, although many, on the other hand, soon recovered. The treatment was abolished, and sulphur baths were substituted to complete the cure.

In institutions, I may say, the treatment of scabies is not always satisfactory where many inmates, as here, are simultaneously affected, for as fast as one is cured he may become reinfected from others or from the bed-clothing, unless proper facilities are afforded for isolation.

I have preserved record of 280 cases in which I have employed naphthol. The diseases were distributed as follows: Eczema, 67; ulcers, 23; scabies, 32; impetigo, 21 (mostly from ped. cap., face, and scalp); pruritus, 10 (1 p. ani, 1 hiemalis, 3 senilis); pityriasis cap., 13 (6 males, 7 females; all more or less associated with alopecia); pityriasis cap., 6 (not associated with alopecia); alopecia premat., 5 (not associated with pityriasis); alopecia areata, 3; pediculi capitis, 12; furunculosis, 8; psoriasis, 7 (1 of scalp; in 2 cases collodion paint was used); ulcerating syphilis, 9 (1 vegetating syph. of nose); dermatitis, 9; pediculi corporis, 5; combustio, 2; epithelioma, 2; ecthyma, 3; acne, 4; tricophytosis, 10 (2 barbæ, 7 cap., 1 corp.); abscessus, 1; œdema and excoriation, 1; prurigo, 2; erysipelas, 1; trauma, 2; intertrigo, 1; favus, 4; sycosis, 3; ecz. marginatum, 2; fissure, 1; herpes, 1; urticaria, 3; pityriasis maculata et circinata, 1; dermatitis exfoliativa, 1; dermatitis squam 1; acne rosacea, 4; total 280.

Eczema.—The 67 cases of eczema represent a variety of forms of the disease. The scaly varieties were found to be those most benefited. In the moist forms the irritation produced by naphthol was too great, unless used in a mild form, as in a starch-paste in strength of from five to fifteen grains to the ounce. The feature of itching was almost always relieved, but the application at first causes smarting if strong. Eczema of the scalp was almost always greatly benefited, and several cases were quickly cured. Internal treatment was usually employed at the same time.

In several cases the use of naphthol was abandoned for tar and zinc, but in almost an equal number, in which tar had produced irritation and aggravated the condition, naphthol was substituted and acted well.

Ulcers.—Old chronic, indolent, and foul ulcers were stimulated by naphthol and usually improved. Syphilitic ulcerations, I found, were more satisfactorily treated by naphthol than by iodoform, and appeared to have the fetor destroyed more effectually, while it assisted the internal treatment in bringing about healing. This was especially noticeable in those extremely foul-smelling syphilitic ulcerations of the scalp.

In scabies, with the exception of a few cases which were seen but once, and the result thus left doubtful, it proved curative in a short time, often after one prescription, and rarely more than two were required. Where the patient can be controlled and the application thoroughly made, it will undoubtedly be found all that has been claimed for it.

Impetigo.—In impetigo and impetiginous eczema, which in most of my cases were associated with pediculi capitis, naphthol ointment gave great satisfaction, and speedily caused a disappearance of the lesions.

Pruritus.—In general idiopathic pruritus, pruritus hiemalis pruritus senilis, and pruritus ani, it invariably acted well, giving quick relief and proving often speedily curative. One patient with an obstinate pruritus ani of many years standing, finds relief from the application of the naphthol soap I have shown. A ten per cent. ointment will cause severe burning if the parts have previously been irritated by scratching, but the burning ceases after a few minutes and the itching frequently does not return for several days. Carbolic acid has been regarded as the great anti-pruritic, but naphthol appears to me quite as efficacious, if not more so, and has advantages over it besides.

Pityriasis capitis.—Dandruff of the scalp, whether associated or not with alopecia, has been without exception cured. (Sometimes, to be sure, relapses are noted, as is the case when other remedies are employed.)

Alopecia, when due to this condition, has in all cases been improved, and in seven of the patients, who were ladies, has been practically cured. There were three cases of alopecia areata in the list treated with naphthol. Two were brothers living together. One made a remarkably rapid recovery while applying daily to the bare spots beta naphthol crystals in substance, rubbing the substance well in with his fingers. The other had obtained, at the time I saw him last, a new crop of fine hairs after using a ten per cent. ointment, having previously had the spots blistered with blistering collodion, and using other stimulating applications. The third case disappeared from observation before the effects of treatment were noted.

In *pediculi capitis* results were always highly satisfactory, the eczema and other changes due to irritation quickly subsiding under the treatment.

In treating *pediculi vestimenti*, or *corporis*, the results were all that could be desired.

In the cases of *furunculosis* mentioned, I used a drachm or half a drachm of naphthol to an ounce of lard or vaseline and avoided poultices. The patients reported that it "drew" well, and in all the cases I shared the satisfaction of the patients. Sulphide of calcium or a tonic was given at the same time, with one or two exceptions.

One case of *carbuncle* upon the neck was likewise treated in this manner, and it gave the patient as little discomfort and healed as quickly and as well without lancing as any I ever treated myself or have seen treated.

Seven cases of *psoriasis* are recorded. One, of the scalp, was cured in a short time. Two now under treatment, in which the collodion is being applied, are doing very well. The patches lose their scales and disappear as quickly as they often do under chrysarobin, without the danger of inflammation of the surrounding skin and the disagreeable feature of staining both skin and clothing.

In *dermatitis* the results have been favorable, but strong applications must not be used.

In *tricophytosis* of the scalp in children I have been pleased with the use of naphthol. In adults where the lesions are upon the skin, and in tricophytosis barbæ, I cannot speak so favorably.

In two cases of papular eczema closely resembling Hebra's prurigo, it acted like a charm. In one, arsenic was given conjointly with it, but the relief from the intense pruritus at least was unmistakably due to the naphthol.

In *favus*, of which there were four cases, its benefit consisted in a removal of the sickening odor and in keeping the heads in good condition in the intervals of more energetic treatment. Its beneficial action was marked and appreciated by the patients themselves. I believe it might prove curative if properly introduced within the hair follicles deep down where the spores have a hiding-place and stronghold.

In *eczema marginatum* and in *urticaria* it appeared to be a valuable application. It has been said to aggravate urticaria, but I have not found it so. In the other affections on the list I do not know that it can be said to have any advantage over hundreds of other local dressings.

Whenever antisepsis is desired, and bacteria or germs are to be destroyed, I believe naphthol has an important rôle to play; it is a valuable detergent and deodorant. In almost all diseases of the scalp it appears to exert an influence for good.

Does naphthol exert any deleterious effects? Under my own personal observation it never has, but I have had reported to me that three patients with scabies in my wards at the Charity Hospital were thoroughly rubbed at the same time with an ointment of naphthol applied to the whole surface of the body. Some hours later they were all seized with symptoms closely resembling those of intoxication from alcohol—singing, shouting, and acting in a dazed and disorderly manner. The house surgeon made the diagnosis of naphthol intoxication, and it was only reported to me after the patients were discharged. The orderly was sure they had had no alcohol, and thought the drug which had been applied had affected them. I have not been able to get a full account of the condition of these men at the time, but hope to obtain a full report from the physician who saw them.

Neisser has reported toxic effects (*Centralblatt für die med. Wissenschaft*, No. 30, 1881).

Kaposi saw a boy suffer from hæmaturia, ischuria, vomiting, unconsciousness, and eclampsia.

Blistering and irritation of the skin have been reported by Squire (*British Med. Journal*, January 14, 1882).

Shoemaker in his valuable paper refers to these reports of poisoning, and gives the results of his experiments to prove the perfect harmlessness of pure odorless naphthol. He experimented on rabbits, and also on medical men who volunteered. Two gentlemen began by taking a quarter of a grain every two hours, and increased the dose, until on the seventh day they were taking five grains at a dose, twice daily, without the least bad effect, and no production of albuminuria. He concludes, then, and his conclusion seems to me highly probable, that the drug used abroad at the time the toxic effects were reported was an impure article, similar, perhaps, to the reddish crystalline mass I have shown to-night.

Be sure, then, the drug you use is pure, and no ill effects need be feared.

Now, a word in conclusion regarding the manner of using naphthol and the various preparations of it.

The mode of applying naphthol most commonly employed by myself has been to order an ointment made with vaseline or lard, containing from five grains to a drachm, rarely more, to the ounce.

I have used lanolin as a base in some instances, but have recently given up its use.

Where a penetrating effect is desired, I have used a salve made in the following proportion:

℞. Naphthol (beta) ..... 5 parts.
Adipis ..... 10 "
Lanolin ..... 85 "
M.

The following paste has given me greater satisfaction than the salve:

℞. Naphthol (beta) ..... gr. v. to xxx.
Pulv. amyli ..... ℥ iij.
Adipis ..... ℥ j.
M. Ft. pastam. Sig.—Apply thickly.

To this oxide of zinc may be added at times with benefit. The fixed dressings with naphthol serve a useful purpose.

Having observed the marked benefit often to be derived from the variously medicated collodia and other fixed dressings, I had a naphthol collodion prepared, and have employed it quite extensively. It acts well in psoriasis, ulcers, tricophytosis, etc.

Mixed with starch powder, talcum, Fuller's earth, or mineral earth, it has given excellent results in moist syphilitic lesions about the anus and scrotum, also in intertrigo, venereal warts, and ulcerations.

I have also mixed the powdered naphthol with boracic acid or oxide of zinc to apply to moist or suppurating surfaces.

Among the various preparations of naphthol we find soaps. In the *Pharmaceutische Rundschau*, October, 1885, Unna has a valuable article on soaps. Among other things, he says that carbolic soap has the least

medicinal value, in his opinion, of all those advocated. The more stable substances—tar, camphor, and naphthol—offer surer success.

Among the soaps he has put forward are a five per cent. naphthol and a five per cent. naphthol and sulphur soap. These are useful where an antiseptic is required for the hands, or for bathing in a great variety of skin diseases. I have found these soaps useful in pruritis and in winter itch.

Aside from the important place I believe naphthol is destined to fill as an antiseptic, I predict for it a place as a remedy in dermatology alongside of tar and many other valuable drugs, rather than as a substitute for them.

102 East Fifty-seventh Street.

SOME NEW FEATURES IN THE MECHANICAL TREATMENT OF LATERAL ROTARY CURVATURE OF THE SPINE.[1]

By CHARLES F. STILLMAN, M.S., M.D.,

Clinical Professor of Orthopedic Surgery in the Woman's College of the New York Infirmary; Orthopedic Surgeon to the New York Infant Asylum.

In the treatment of lateral rotary curvature of the spine, the reduction of the deformity by traction should be effected before any other measures are adopted, and although of primary importance, too little emphasis has been placed by orthopedic writers upon this most necessary procedure.

In the erect position of the body, the head and upper extremities constitute a burden, which naturally presses the vertebræ together. As a result of having its constituent vertebræ forced together in the abnormally rotated position characteristic of this deformity, the spine becomes restricted in its movements and locked; and this locking is so firm and unyielding while the burden is borne upon it, that this burden must first be removed by *traction* before other treatment can be thoroughly effective.

It is simply useless to attempt to overcome the abnormal curves by mechanical means, however perfect, without first exercising traction; and the great variety of ingenious braces which have during the history of modern surgery been devised to relieve this deformity, without success, are simply monuments to attest the truth of this statement.

Traction for the relief of lateral rotary curvature may be directed in either of four directions—(1) *horizontal*, (2) *vertical*, (3) *oblique*, or (4) *curved*. The first, or horizontal traction, is the governing principle of the various flat extension couches, which are now happily obsolete; while the second, or vertical traction, is the principle on which is based the practice of suspending the patient in a properly devised sling, and while thus suspended, a plaster-jacket is usually applied to retain the improved position thus secured.

When the patient is suspended, it will be noticed that the abnormal curves have become modified by the traction force of the suspended weight. The vertebræ being thus unlocked and freed from the pressure of the burden (the head and upper extremities), tend to rotate into their normal relations; and if the tone of the muscular system be not too much impaired by long continuance of the deformity, and no absorption changes have been caused in the osseo-ligamentous and cartilaginous structures by pressure, so that when the patient's spine resumes its burden no reappearance of the abnormal curves takes place, no mechanical after-treatment with braces will be necessary.

If, however, the suspension is followed by the resumption of the abnormal curves, *brace-treatment* becomes a positive necessity, and may be either *passive* or *active*.

A *passive brace* simply serves to hold the spine in the position assumed when the brace was applied; while an *active brace*, by means of levers or elastic force, tends in addition to remove the deformity.

After employing suspension or vertical traction to unlock the spine, Sayre advocates the employment of the plaster-jacket as a splint to retain the spine in a correct position, and thus prevent, as far as possible, resumption of abnormal curves.

Now, the *plaster-jacket* is a *passive brace*, and is not actively effective even in this capacity, owing to the fact that it embraces only part of the spine. Especially is this the case where the primary curvature is high, for the jacket in these cases, holding but half of the spine, the latter, being undulatory in its movements, is not encompassed to prevent entire resumption of its abnormal curves when the superincumbent weight is again sustained.

Besides, the plaster-jacket, being passive, encircles the trunk in a rigid frame, which tends to restrict respiration and the proper exercise of the muscles; and thus, when its use has ceased, if there has been no treatment locally applied to the feeble muscles, etc., relapse is sure to follow.

To avoid this and to allow facilities for local treatment, the jacket has been divided anteriorly, which admits its removal for exercise, etc., but once so divided, it does not prevent the resumption of the abnormal curves to the same extent as before; so that, while the suspension—*i.e.*, vertical traction—unlocks the spine, the passive plaster-jacket constitutes a very inefficient agent for permanent cure of the deformity, and should be prescribed if an *active brace* can be obtained.

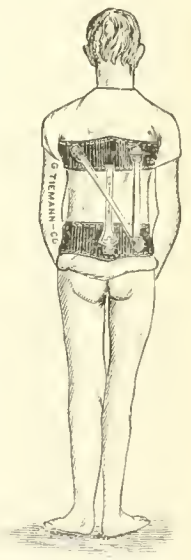


Fig. 1.—Stillman's Vertical Extension Brace for Lateral Rotary Curvature.

Meeting these difficulties in practice suggested to the writer a plan for overcoming them by means of an active brace, which would exert vertical traction by the use of extension-rods, and in 1881,[1] he read a paper before the Surgical Section of the American Medical Association, illustrating a method for dividing the plaster-jacket into two segments and connecting these segments by extension-rods provided with facilities for motion in various directions, and with elastic cords to assist the weakened muscles and produce oblique elastic tension upon the segments of the brace, and thereby upon a corresponding portion of the trunk and spine—the *idea* being to create an *active* jacket, instead of a passive one, which should produce vertical extension, of course not to the extent produced by suspension, but still to an effective degree, and yet allow exposure of surface for the local treatment indicated (see Fig. 1).

Since that time the vertical extension-jacket has been modified to suit the various forms of the deformity, without, however, changing the essential principles. The stretching has in some cases been made by elastic extension-rods, instead of slotted bars and clamps, or the cog and key; and in some cases the rods have been placed on four sides of the body, instead of two, for increased support.

In some cases, also, when the curvature has been high up, a headpiece has been added to allow vertical extension of the whole vertebral column; but these are all modifications which interest the instrument-maker rather than the surgeon, and do not affect the principles involved.

In this manner an *active splint* was formed, which not only partially retained the effect upon that part of the

[1] Read before the Orthopedic Section of the New York Academy of Medicine at its annual meeting, Friday evening, January 21, 1887.

[1] The writer first established his priority, in the matter of dividing the plaster-jacket, in The Medical Record, 1879.

spine between the segments produced by suspension, but also, so long as it was worn, produced permanent tendencies toward the restoration of the back to its normal condition, without interfering with any measures of a therapeutic or physical nature for the amelioration of the disease.

There is, however, a limit to the efficiency not only of splints founded upon this plan, but also to vertical traction itself.

This is primarily owing to the fact that traction in this direction cannot, in severe cases, bring to bear sufficient *oblique* force to overcome extensive rotation; for the value of vertical traction is limited by the amount of weight which is suspended—this being the active agent in the reduction of the deformity, and in many cases sufficient weight cannot be thus utilized without discomfort to the suspended patient; and if the vertical traction-brace be used in such a case, sufficient stretching of the spine to lift the superincumbent weight from between the segments of the brace cannot be produced without too much infringement upon the soft parts, so that there was still something lacking to complete success.

To supply this need the writer devised the method of *backward oblique traction* in the treatment of this spinal affection (see Fig. 2).

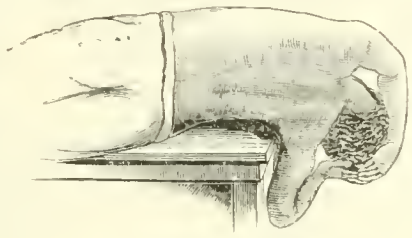

Fig. 2.—Backward Oblique Posture for Reduction of the Deformity in Lateral Rotary Curvature.

This method, as its name indicates, consists in *stretching the spine by traction exerted obliquely backward*, accompanied by *direct pressure against protruding parts*—a feature not possessed by vertical traction, and which tends to reduce the deformity more completely.

To illustrate this principle in detail the patient is placed upon a table in the sitting position, the buttocks being at a distance from its edge corresponding to their distance from the convexity of the dorsal deformity.

The patient then gradually *reclines backward, twisting* at the same time in a direction *opposite* to the twist of the curvature, until the spine is dragged upon by the weight of the head and upper extremities. This, in severe cases, is at first painful, for it tends to exactly *reverse* the abnormal curves. The traction-force is the *burden* which the spine usually bears, and which is the cause of the deformity, so that we have the very weight which, pressing constantly on the spine, causes the deformity, now used as a traction-force to relieve it.

In addition to the *traction*, which from the position assumed by the patient is exerted in an obliquely backward direction, we have *pressure* exerted upon the prominent scapula and ribs by the edge of the table. This is a corrective feature not found in vertical traction, and proves very efficacious.

It may at first seem that such a position as above described would be harsh and painful to the patient, but this is not true, for; practised daily as an exercise, it soon becomes not only tolerable, but grateful to the patient, causing, as it does, the spine to become flexible, and tending to obliterate the deformity more rapidly than any other procedure.

Another method of obtaining this backward oblique traction is to *reverse the process*, allowing the lower extremities to fall over the edge of the table in a position opposite to that of the deformity, this being particularly efficacious in curvatures in which the lumbar region is most involved.

These *postures* should be practised as exercises, and in the less severe cases, accompanied by electricity, gymnastics, etc., the use of the double-bar trapeze, and other adjuncts, is sufficient to correct the deformity without the use of a brace; but if the muscles have become so weakened, or anatomical changes have taken place in the osseo-ligamentous structures, so that the normal curves cannot be retained when the erect posture is assumed, a brace will be found necessary.

This *brace* should be *active*, not passive, and so constructed as to imitate as far as possible the forces exerted in the posture shown in Fig. 2.

Fig. 3.—Illustrating the Curvature when Patient has no Support.

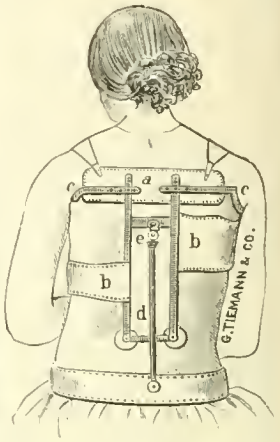

Fig. 4.—Illustrating the Principal Features of Stillman's V-Lever Brace when applied to Patient shown in Fig. 3.

It should insure a *backward oblique traction* and *forward oblique pressure* corresponding to the backward oblique traction-force exerted by the *gravital-force* and the forward oblique pressure occasioned by the *table*.

The brace is made in two parts, and is entirely unlike anything ever before introduced into orthopedic surgery for the treatment of this deformity (see Fig. 4).

A glance at the human skeleton shows that both lumbar and cervical vertebræ move freely upon one another as compared to the *dorsal*, which are restricted in their movements. This dorsal portion of the spine is therefore used as a base for the brace, instead of the pelvis, as in other braces.

The brace is constructed in *three parts*—dorsal, pelvic, and cervical. The *first*, or *dorsal*, consists of a broad pad placed high up across the shoulders, and from this descend two metallic strips, terminating in pads in the lumbar region. From these strips the stiff metallic semi-girths (bb) pass practically around the body, the upper one being over its protbuerant scapula, and the lower one carried around to press upon the protuberant ribs anteriorly.

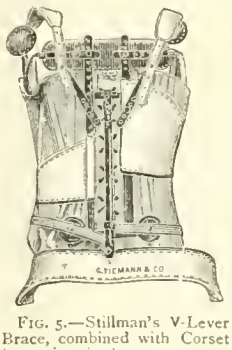

Fig. 5.—Stillman's V-Lever Brace, combined with Corset (posterior view).

From each side of the transverse pad (a) pass axillary crutches (c, c), terminating anteriorly in large pads which lift and press the shoulders backward without impinging or pressing upon the infraclavicular spaces.

The material of which these crutches are constructed is of sufficient firmness not to yield to the twisting efforts of the patient, although they may be bent into any position by the orthopedist's hands, and they serve a very important purpose in regulating the position of the shoulders and upper extremities.

This dorsal portion of the brace may be incorporated into a corset if desired (see Fig. 5), several of the straps which are used to fasten it firmly to the body being omitted in the drawing, as they might tend to confuse

the reader in understanding the construction of the brace.

The *pelvic* portion of the brace consists of a padded pelvic girth which locks in front, is very stiff, and is attached to the dorsal portion by a long bar (d), which terminates superiorly in my compound clamp (e). This clamp has been described before in various journals, and permits the pelvic portion to be fixed at three different angles with the dorsal, to which it is attached. By it we may exercise a *rotary active* force, *an antero-posterior force*, and a *lateral* force, thus bringing a compound twisting force to bear upon the spine. If the dorsal portion of the brace be *first* securely fastened to the body and the clamp regulated properly, when the pelvic portion is secured, we have the body held hyper-erectly, the protruding scapulæ and ribs pressed upon, and the shoulders squared by an *active backward latero-oblique force* from which the patient cannot escape.

The *cervical* portion is only necessary when the curvature is high, and then a chin-piece is used, attached to the dorsal portion by a bar provided with the compound clamp already described; but this portion of the brace is not shown in the drawing. In applying this brace the patient is first suspended so that the abnormal curves may be reduced as much as possible before its application. It will then tend to retain the favorable position produced by the suspension, and, indeed, improve it by means of the active twisting force it brings to bear.

But the use of a brace alone is but a small portion of the treatment of this curvature. *We must also aim to strengthen the deficient muscles during such time as traction is being exerted upon the spine itself*, and for this purpose the writer has recently devised two frames, which are unique and accomplish the purpose admirably with but little fatigue to the patient.

Fig. 6.—Stillman's Vertical Frame for Backward Curved Traction during Exercise.

The first, or vertical, frame (see Fig. 6) produces suspension on the curved board or *curved traction*, and while thus suspended, either partially or wholly, the patient takes arm exercises by means of the weights and pulleys with which the apparatus is provided.

The second, or horizontal, curved frame (see Fig. 7) produced the same results, but perhaps not to the same degree; and their conjoined use not only increases the vitality of the patient by expanding the chest and strengthening the muscles, but tends to diminish the curvature very materially.

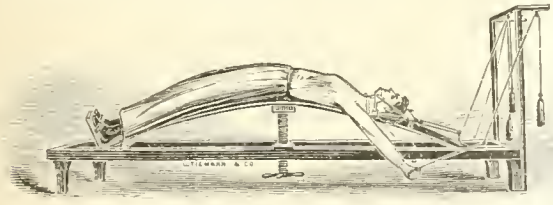

Fig. 7.—Stillman's Horizontal Frame for Backward Curved Traction during Exercise.

The horizontal frame is also used by phthisical patients with good effect, and also in cases of persistent backache, with or without spinal irritation.

In conclusion, it is my opinion, based upon many cases of this deformity, that the best results are obtained by the conjoined use of an *active brace* and proper exercise upon curved frames.

A brace alone is of but little use, serving merely to hold the body erectly; but to exert any *curative power it should be made to fit the patient accurately and be readjusted often*, so as to exert its active effects through all the stages of improvement; and, in addition, the patient should be obliged to take systematic exercise, and, if necessary, should receive the benefit of massage, electricity, and other tonics. The diet and habits of life should be regulated carefully, and all work avoided which tends to increase the deformity.

THE PATHOGENIC MICROBE OF "ACUTE CATARRHAL CONJUNCTIVITIS."[1]

By J. E. WEEKS, M.D.,

RESIDENT ASSISTANT SURGEON OPHTHALMIC AND AURAL INSTITUTE.

The form of conjunctivitis to which I call your attention is described under different names by different writers. Thus Travers, Lawrence, Mackenzie, Howard, and others term it catarrhal ophthalmia, Mackenzie giving as synonyms catarrhus oculi, ophthalmia purulenta mitior, and conjunctivitis puro-mucosa catarrhalis. Stellwag, Saemisch, Wells, Williams, Noyes, and others give it the name of catarrhal conjunctivitis. Nettleship calls it muco-purulent catarrh. The severer forms of this disease are termed blennorrhœa, and on the occurrence of certain complications the same disease is known under other names. Howard appears to be the only writer who regards this form of conjunctivitis as a distinctive disease. He writes: "This disease is purely specific, and differs in every respect from all other diseases of the conjunctiva. It never runs into perfect chemosis or induces sloughing of the cornea." Mittendorf describes the milder forms of this affection under the name of "simple inflammation of the conjunctiva."

If we glance at the causes of catarrhal conjunctivitis as given by the various writers, and consider some of the expressions of these writers, we must conclude that under this head a number of distinct diseases are included. The causes briefly are as follows: Atmospheric—sudden changes in the temperature, cold rains, draughts of air, exposure to east or west winds, night air, etc. Mechanical—dust and smoke, foreign bodies, wounds; combustion with steam, lime, powder, acids, etc. Transmission from contiguous tissue—as in facial erysipelas, catarrh of the nasal cavities, dacryocystitis, eczema of lids, hordeoli, pityriasis, etc. Accompanying the eruptive fevers—as scarlet fever, measles, small-pox, etc. Asthenopic—as in astigmatism, hypermetropia, insufficiency of ocular muscles. Work with bad illumination, protracted use of eyes, bright light, violent emotion of the mind, high living, use of ardent spirits, etc.

Contagion as a cause of conjunctivitis is admitted by almost all writers. Saemisch goes so far as to say that all discharges from the conjunctiva are capable of producing conjunctivitis when brought in contact with the normal conjunctiva. Mackenzie, Howard, Wells, Williams, and Noyes consider conjunctivitis to be infectious through the atmosphere, but none hint at a possible bacterial origin. In the mild form of conjunctivitis, usually termed catarrhal, brought on by exposure to cold winds, rain, snow, particles of dust, and larger foreign bodies entering the conjunctival sac, exanthematous fevers, errors of refraction, insufficiencies of ocular muscles, close work with insufficient illumination, high living, etc., there is profuse lachrymation and small secretion of mucus with but few leucocytes, but no pronounced muco-purulent secretion. This form does not run a specific course, but subsides as soon as the cause is removed. It is probably not contagious—at least, we do not see it spreading throughout families and communities. In conjunctivitis resulting from more severe injuries—as from combustion from lime, steam, and powder, laceration of the lids and

[1] Read at the Academy of Medicine before the Section in Ophthalmology and Otology, January 17, 1887.

conjunctiva—if one eye only is affected, even if the discharge is purulent or muco-purulent, the other eye remains unaffected, and there is no spread of the conjunctivitis in the family of the patient. Quarantine precautions are seldom resorted to in these cases, as intact, normal conjunctivæ are not affected by contact with the discharge.

There is another form of conjunctivitis, specific in nature, which, in its early stage, is described under this head. Later it develops into trachoma and is then described as such. It is admitted to be contagious, and is the form in which Michel and others have found a coccus, which Michel asserts to be the cause of the disease in one epidemic at least.

We might mention a number of other forms, more or less distinctive, included under the name of catarrhal conjunctivitis in one or all of their stages, but will close the list with one other form, the one that will be described in this paper. In this the discharge is muco-purulent and is highly contagious. The disease runs a specific course and does not tend to destruction of the cornea or to develop into trachoma. It is the ordinary contagious muco-purulent conjunctivitis met with.

The general signs and symptoms of this form of disease are as follows: During the first twenty-four hours after the receipt of the virus nothing abnormal is noticed. In the second twenty-four hours the following occurs in the order named: Slight itching and burning sensations in the lids, congestion of the palpebral conjunctiva, the sensation as of a foreign body in the eye, sometimes very annoying; increased lachrymation, and a not very profuse secretion of mucus, which contains a few pus-cells. On the third day the above symptoms are aggravated, the ocular conjunctiva becomes injected, and the appearance popularly known as "pink eye" is present. The secretion contains more pus-cells and is much more profuse; the lids are glued together in the morning. The secretion, which generally does not mix with the tears (distinguishing it from the pyorrhoic pus of Stellwag), lies in stringy masses in the conjunctival sac, or is heaped up in harder yellowish masses at the inner canthi, the watery or fluid portion having been carried into the nasal cavities by the canalicular system of the lachrymal apparatus. On the fourth day the inflammation usually reaches its height. Then all the symptoms are more marked. Frontal headache and coryza frequently occur, the former in adults only, and the temperature of the body is usually slightly elevated. But slight photophobia is experienced. This stage may last for a week or ten days, with evening exacerbations, but it usually subsides in from three to five days. Some obscuration of vision occurs from deposits of secretion on the cornea. More or less swelling of the lids is present, and during the latter part of the acute stage considerable swelling of the papillary body is observed. The acute passes into the subacute stage, in which the ocular conjunctiva becomes normal, the secretion less profuse and thicker, lachrymation becomes less than normal, no photophobia is present, and the irritation experienced is less. At this stage the enlargement of the papillary bodies often resembles the so-called follicular conjunctivitis of Saemisch. If not properly treated the subacute passés into the chronic stage, in which there is marked congestion of the palpebral conjunctiva, some secretion, and a sensation of dryness due to insufficient lachrymation. This condition may last indefinitely.

Report of cases.—On March 21st Dr. R. O. Born kindly sent a patient to me who was suffering from acute conjunctivitis, with the request that I should examine the rather profuse muco-purulent discharge microscopically. The patient, Anna F——, aged thirty, first noticed that her eyes were sore three days previous to her visit to me. *Status præsens.* The ocular and palpebral conjunctivæ are greatly congested, lids slightly swollen, quite marked photophobia, profuse lachrymation, and mucorpurulent discharge. A cover-glass preparation of the secretion was made, stained with a watery solution of gentian violet, and examined with a one-twelfth oil immersion. *Large numbers of small bacilli were found.* These were aggregated on and in the pus-cells, and some were free in the mucus. The patient complained of frontal headache and had some coryza. By the use of constant cold applications for three or four days, and the subsequent use of mild astringents, the patient recovered in two weeks from the beginning of the attack.

There were two children in the family, one of twenty months and one of four years, both of whom had sore eyes. These cases had passed into the chronic stage. There was no photophobia, and the children did not appear to be troubled by the scanty discharge. The first had had conjunctivitis for two months. The second was a case of six weeks' standing. In both the palpebral conjunctiva was congested and was discharging muco-pus. The secretion from both cases contained many bacilli, such as were found in the secretion from the mother's eyes. By keeping the eyes clean and the use of a zinc collyrium, both children recovered in one week after treatment was commenced.

In frequent examinations of conjunctival secretions at the Ophthalmic and Aural Institute, for some months previous to March 21st, I had never met with this form of microbe. With a view to determining how frequently cases like the ones described occurred, all the secretions from conjunctival diseases that presented subsequently were examined. The bacillus did not appear again until May 21st, when

Peter C——, aged twenty-three, presented himself for treatment. He was attacked on May 17th, and suffered severely. The pain, irritation, swelling of lids, and profuse muco-purulent discharge made it impossible for him to continue his vocation, which was that of a pedler. He had slept but little since the 17th. By the use of cold applications and astringents he recovered in five or six days, but returned again in three weeks with a fresh attack, as severe as the first, which readily responded to the same treatment. On inquiry I found that his wife, three children, and a servant-girl, still had, or had recovered from, a similar form of conjunctivitis. They were attacked as follows:

Russel C——, aged five. Attacked May 1st, both eyes. Discharge still persists.

Thomas C——, aged two and a half. Attacked May 4th, both eyes. Discharge still persists.

Joseph C——, aged fifteen months. Attacked May 7th, both eyes. Muco-purulent discharge still persists.

Eliza C——, aged twenty-eight. Attacked May 9th, right eye only. Much irritation and pain. Recovered.

Katie O'C——. Attacked May 16th, right eye only. The muco-purulent discharge still persists.

When two eyes were affected the disease appeared in one first, following in the other in from one to three days. The children played and slept together. By cleanliness and the use of a zinc collyrium all the members of this family recovered in a few days.

In order to call attention to the complications that arise in this disease the following cases are given:

May 22d.—Gustave V——, aged one. Attacked May 8th. The ocular and palpebral conjunctivæ are still swollen and congested. Muco-purulent discharge profuse. A *false membrane* covers the tarsal conjunctiva of both upper lids, which when removed leaves minute bleeding-points. The membrane is tenacious and comes off whole. The membrane renewed itself after removal, and in spite of repeated removals persisted for about ten days. The child recovered by the use of cold applications, and a zinc collyrium applied after the membrane had almost disappeared. Other members of the family were affected with muco-purulent conjunctivitis at about the same time, without the formation of false membranes. Specimens of the secretion from all showed the small bacillus.

June 2d.—William F——, aged two. Attacked on May 29th, right eye only. June 4th, left eye discharging

muco-pus. June 7th, a few marginal phlyctænulæ appeared on the right eye. With the same treatment as in the previous cases the patient soon recovered. Other members in the same family had the uncomplicated muco-purulent conjunctivitis.

October 20th.—Clara M——, aged eighteen months. Attacked, October 13th. The muco-purulent discharge has been quite profuse. *Status præsens:* The lids are much swollen but are soft. The discharge, which is muco-purulent, is not very profuse, corneæ clear, a dusky white, tenacious false membrane occupies the tarsal conjunctiva of both upper and lower lids, being very thin and narrow below, wide and about one millimetre in thickness above. The membranes commence at the margins of the lids and cover the tarsal conjunctiva, extending to the fornix above. The membranes, although quite adherent, came off whole by rather vigorous rubbing with the sponge, leaving a number of small bleeding-points. This case resembled diphtheria somewhat, and was entered as such, with an interrogation point, by the receiving surgeon. Cold applications were recommended. October 25th, membrane still present but not so dense; swelling of lids less marked. The membrane disappeared in ten days from the first observation, and the child was well shortly afterward. Corneæ intact. The secretion contained many bacilli.

Microscopical examination in the fresh state showed the membrane to be composed of leucocytes, blood-corpuscles, epithelial and short spindle-cells and débris, all contained in a fine meshwork of fibrin. Bacilli, few in number, were found scattered throughout the mass. Microscopically and macroscopically the membrane resembles that found in the so-called croupous conjunctivitis.

November 1st.—Benjamin B——, aged nine, has had a muco-purulent discharge from the eyes nine days. A false membrane is present in this case, with the same characteristics as the one just described, except that the process is not so severe. Recovery without injury to the corneæ occurred. The membrane was present a little more than one week.

From the fact that in the spring of 1884 the disease was wide-spread throughout the southern part of the New England States, it would appear to be epidemic and transmissible through the atmosphere.

From the following, it appears very probable that this form of conjunctivitis may become endemic:

At the New York Infant Asylum, Mount Vernon, muco-purulent conjunctivitis has affected a large number of the inmates every year, for some years back, beginning about the latter part of August and disappearing in January. In 1885 almost all the inmates, mothers and children, were affected. The disease appeared again in 1886, and although those suffering from the affection were isolated as soon as the discharge showed itself, nearly all of the inmates, to the number of three to four hundred, were attacked. By the courtesy of Dr. Coggeshall, the physician in charge, I visited the wards of the institution on December 20th last, and examined some of the inmates. At that time there were more than one hundred cases of conjunctivitis present, of from two days' to six months' duration. The patients had been treated from the beginning with a one per cent. solution of the nitrate of silver applied twice daily. The average duration of the disease in these cases was about four weeks. Phlyctænulæ had been observed in but very few cases. I saw one case in an adult. Blepharitis ciliaris occurred in a small number. False membranes had been observed in five or six of the severer cases, the membrane usually lasting six or eight days. One of the cases that I saw, that had lasted six months, had had a false membrane. One of the doctors and two of the nurses in attendance had been affected. There was no tendency whatever to development into trachoma. Numerous specimens of the secretion were taken for microscopical examination. All contained the small bacillus in greater or less numbers. In none of the cases occurring at this institution had the cornea been affected.

In one of the institutions for the care of destitute children in this city, I observed, in the early part of June last, ten cases of this form of conjunctivitis. They were isolated, and recovered in a short time by the use of cold and astringents. The disease appeared again among the children in September, and within ten days about forty-five children were affected. These were isolated, and were treated with cold applications and a zinc collyrium. The average duration of the disease in these cases was two weeks. False membrane occurred in two or three cases, phlyctænulæ in two, blepharitis ciliaris in two. There was no tendency to the development of trachoma, and no injury to the cornea in any case.

If this form of conjunctivitis is a specific disease, as I hold it to be, the secretion (selected carefully to prevent external contamination), if introduced into the normal conjunctival sac, should produce this form of conjunctivitis and no other. Saemisch, in speaking of this form, writes that the disease produced by contagion does not always resemble the case from which the secretion is obtained. As is known to be the case in other specific diseases, as scarlet fever, small-pox, etc., there is in this a wide range in the severity of the cases. Within this range the following report of experimental cases will, I think, prove the position taken by Saemisch to be untenable. The experiments were made with the purpose of fixing beyond a doubt the contagious character as well as for the purpose of deciding the specific nature of the disease.

March 22d.—The eyes of two rabbits were inoculated with secretion taken from the first patient. No inflammatory reaction followed.

May 21st.—Inoculated two rabbits' eyes again with fresh secretion. Result as before. No reaction. As the rabbit's conjunctiva was not susceptible to the disease, I determined to inoculate the human conjunctiva of eyes where vision had been lost.

Case I.—May 22d.—J. B——, aged fifty-four. Right, phthisis bulbi; left, old irido-cyclitis. Both eyes were inoculated with a small amount of muco purulent discharge taken directly from the conjunctival sac of Peter C——. Half an hour before inoculating the eyes the conjunctival sac of the patient had been cleansed with a $\frac{1}{5000}$ solution of sublimate. The eyes were then kept closed until the secretion formed, after which it was transferred to the normal conjunctiva with a sterilized platinum wire.

May 23d.—No change in the appearance of the conjunctiva. No marked symptoms.

May 24th.—Hyperæmia of palpebral conjunctiva; increased lachrymation; some muco-purulent discharge; no pain.

May 25th.—Quite severe pain at night; patient unable to sleep; lids swollen; ocular conjunctiva injected; profuse muco-purulent discharge. The patient was kept from contact with others and no treatment except frequently washing with water was employed, until the end of the second week, at which time the congestion of the ocular conjunctiva had subsided. Thickening of the palpebral conjunctiva remained and the discharge persisted. From this time zinc was used, and the patient recovered in four weeks from the time of inoculation.

Case II.—May 22d.—J. C——, aged fifty-eight. Right eye inoculated as in Case I.

May 24th.—Lids of right eye glued together in the morning; some discharge of muco-pus during the day.

May 25th.—The inflammation is at its height; ocular conjunctiva deeply congested.

May 29th.—The left eye has become affected and is discharging muco-pus. The subsequent conduct of this case corresponds to that of Case I.

In all, the normal conjunctivæ of five sightless eyes were inoculated, in four of which the typical muco-purulent conjunctivitis was produced. The eyes of one patient who was suffering from trachoma were inoculated

The acute form was produced, with the result of benefiting the trachoma.

The bacilli were present in the discharge from all of these cases as long as it lasted.

After a close study of fifteen or twenty cases of this disease I came to the conclusion that it possessed no tendency to destruction of the cornea or to the formation of granulations. Feeling sure of this, I inoculated my own eye in order that I might more carefully study the signs and symptoms. On June 4th at 3.30 P.M. Dr. F. Smith, at my request, placed a small amount of muco-purulent secretion which had been removed from the conjunctival sac of a patient, with a platinum rod, into the lower conjunctival sac of my left eye.

June 5th.—In the afternoon a very slight burning sensation in the upper lid was experienced.

June 6th.—Slept well. Lids of left eye glued together in the morning (forty hours after the inoculation was made). Ocular and palpebral conjunctivæ congested; lids feel a little stiff and swollen; no chemosis. The discharge of muco-pus was very little until after noon, when it became quite profuse. At 9 P.M. the irritation became so intense that cold applications, by means of iced cloths, were resorted to. This was kept up until twelve o'clock.

June 7th.—The eyelids do not feel as sore as they did last evening; discharge profuse. The painful sensations and the quantity of the discharge increased toward evening. Temperature, 100° F.; pulse accelerated; some frontal headache. Cold applications, commencing at 5 P.M. and continued until 11 P.M.

June 8th.—Was a repetition of June 7th.

June 9th.—Cold applications all day and late into the night.

June 10th.—Eye much better; cold applications discontinued.

June 11th.—Eye much worse; stiffness of lids; irritation and discharge increased. Hypertrophy of the papillary bodies above and below. Ice-applications far into the night.

June 13th.—Eyelids painful, but less secretion. Ice-applications in the evening. As the lids became glued together often, I rubbed their margins with vaseline combined with the yellow oxide of mercury, one-half per cent.

June 15th.—Eye much better. Ice-applications discontinued.

June 19th.—Ocular conjunctiva almost white; lids glued together in the morning. Papillary bodies swollen.

July 4th.—No secretion for some days, but a dryness of the lids, from insufficient lachrymation, becomes very annoying whenever an attempt is made to read or use the eyes for close work, by insufficient illumination. In about six weeks from the time of the inoculation the eye was in a normal condition, not a trace of the inflammatory action remaining.

The bacilli were present in the secretion as long as it persisted, but they were vastly reduced in number after the cold applications had been made two days.

"*Cultivation.*—By the kind assistance of Dr. T. Mitchell Prudden, attempts were made to cultivate the small bacillus on agar and gelatine in tubes and on plates from secretion from the first case and from the case of Peter C——, without success. Peter C—— went to the laboratory and the secretion was transferred directly from the conjunctival sac (after having thoroughly cleansed the sac and permitted fresh secretion to form) to the tubes and plates. Although the conditions were made as favorable as possible, the *bacillus did not develop*. On particles of pus transferred to the tubes and kept in the breeding oven, at a temperature of about 36° C., the bacillus developed, but it could not be induced to feed on the agar or gelatine."

Subsequent investigations were carried on at the Ophthalmic and Aural Institute with apparatus that Dr. Knapp kindly placed at my disposal.

An endeavor was made to render the agar, which was a one per cent. preparation, acceptable to the bacillus by the addition of a little sugar, in some tubes, increasing its alkalinity in others, and by making it more acid in others, *without success*. I did not experiment further with the gelatine, which was a ten per cent. preparation. Conceiving the idea that possibly the agar was the objectionable factor, a food jelly which contained only about 0.5 per cent. of agar was prepared. The *bacillus developed* rather feebly in this preparation in tubes, but would not grow on plates. Having found a medium on which the bacillus would develop, although feebly, my next endeavor was to make a *pure culture*. The bacillus in the tubes was contaminated with a club-shaped bacillus (or one that soon became clubbed) which developed about as rapidly as the small bacillus, and repeated attempts to separate the two proved fruitless. It was very easy to obtain a *pure culture* of the *clubbed* bacillus, as it grows, quite readily, on one per cent. agar and on ten per cent. gelatine. Very many attempts were made to obtain a pure culture of the small bacillus by employing the plate method. The same medium on which the bacillus would grow in tubes would not support it on plates. An attempt was made to produce a pure culture by inoculating many tubes from an attenuation of the mixture, in "normal saline solution," without success. In the one-third to one-half per cent. agar in tubes the bacillus, with its contamination, was carried to the *sixteenth generation*. Repeated attempts have been made to cultivate the small bacillus on coagulated, sterilized blood-serum, but all these have failed to carry it beyond the second generation. It develops in beef-tea.

Its development on agar is as follows: But little or no growth can be observed during the first twenty-four hours. At the end of forty-eight hours a slight haziness appears along the tract of the needle, and on the surface of the agar a very small patch is noticeable; this is of a pearly color and possesses a glistening surface. By the formation of concentric colonies the growth extends for a short distance from the point of puncture on the surface of the agar. The growth reaches its height in from five to seven days, at which time the above-described appearances are but slightly exaggerated. The bacillus then gradually degenerates, breaking up into small particles which take the stain poorly. I have not seen the well-formed bacillus in any tube-growth later than *one month* after the tube was inoculated, when the tube was kept at a temperature of 36° C. The club-shaped bacillus retains its form and vitality much longer. The 0.5 per cent. agar is the best medium that I have found on which to cultivate the small bacillus; it leaves, however, much to be desired which further experiments will probably satisfy.

The method of inoculating tubes with the secretion has been to thoroughly cleanse the conjunctival sac with clean water and cotton, direct the patient to keep the eyes closed, and, after five or ten minutes, to transfer a small portion of the newly formed secretion from the bottom of the lower conjunctival sac to the tube, using a previously heated platinum rod for the purpose. An even temperature from 34° to 38° C. is most favorable for the development of this microbe; it is also necessary to have abundant moisture. I have never succeeded in making a cultivation of this bacillus below a temperature of 30° C., nor on agar from which the water was in part removed.

Description.—The bacillus varies considerably in length, being from one to two micro-millimetres long; in thickness it is always the same, namely, about 0.25 of a micro-millimetre. Compared with the tubercle bacillus, it is of about the same thickness, but is shorter. In specimens from cultures on agar I have observed a number of the bacilli joined end to end, forming quite long threads (6 to 12 together), the division between individual bacilli being very indistinctly marked. There was no tendency to a double arrangement, as in bacillus subtilis.

The formation of spores is not determined. The small bacillus stains readily with watery solutions of fuchsin, gentian violet and methylene blue, taking the stain a little less deeply than do the cocci and bacilli ordinarily met with. When the bacillus commences to dengenerate it stains much less readily. It does not stain well with Bismarck brown, ammonium, or picro carmine, or with hæmatoxylin. Attempts at double-staining have, so far, proved unsatisfactory. In staining sections of the conjunctiva, Gram's method with gentian violet has given the best results. I find nothing peculiar to this bacillus in the effect produced upon it by the various acids, alkalies, alcohol, chloroform, or ether. In strong nitric or sulphuric acid the bacillus is soon destroyed. If colored with gentian violet or fuchsin, the bacillus is quickly decolorized when treated with alcohol or a ten per cent. solution of either nitric, acetic, hydrochloric, or sulphuric acid; taking the color again readily after the decolorizing agent is removed by washing with water.

Inoculation experiments.—Not having succeeded in making a pure cultivation of the small bacillus, pure cultures of the clubbed bacillus were made, and experiments conducted with this and with the mixture.

Experiments with the clubbed bacillus.—No. 1. The right eyes of two rabbits were inoculated by placing some of the pure culture into the lower conjunctival sac. Absolutely no inflammatory reaction occurred.

No. 2. The eyes of two rabbits were inoculated by introducing the bacillus into the anterior chamber, after piercing the cornea with a cataract-knife which had previously been dipped in a thick emulsion of the germs. The wounds healed without inflammatory action. The human conjunctiva was then tried.

Case I.—July 10th.—T. B——, aged twenty. Right eye inoculated by placing a small amount of the pure cultivation (seventh generation) in the conjunctival sac. The patient was under observation one week. *No reaction.*

Case II.—July 10th.—I. M——, aged forty-two. Right eye inoculated as in case No. 1. No reaction.

Case III.—August 8th.—D. L——, aged six. As in case No. 1. No reaction.

Case IV.—August 8th.—S. G——, aged six and a half. As in case No. 1. No reaction.

Case V.—August 13th.—W. W——, aged seven. As in case No. 1., with sixth generation. No reaction.

The above five inoculations of the human conjunctiva and four of rabbits are sufficient to prove the innocence of the clubbed bacillus in the production of acute conjunctivitis and in the formation of pus.

Experiments with the mixture of the small and club-shaped bacilli.—In these cultivations the small bacillus largely predominated.

Case I.—July 29th.—M. I——, aged six. Right eye inoculated from a *fifth generation*, proceeding as above.

July 31st.—The ocular and palpebral conjunctivæ of the *inoculated eye* are markedly congested, and are secreting a small amount of muco-pus; profuse lachrymation; no photophobia, and but slight pain. Left eye normal.

August 2d.—The congestion of the ocular and of the palpebral conjunctivæ of the right eye is very intense. Profuse discharge of muco-pus, which collects at the inner canthi, escaping over the cheek at this point. Lachrymation, slight photophobia, some pain in the lids, and mild coryza. The *left eye* is becoming injected, probably having been inoculated with the discharge from the right eye.

August 4th.—Both eyes present a typical picture of acute conjunctivitis, with intense congestion and slight swelling of the ocular and palpebral conjunctivæ. Chemosis not present; swelling of lids marked. Continuous cold applications were ordered.

August 8th.—The ocular conjunctiva is becoming white. The discharge still continues, but is less in quantity and is thicker.

August 10th.—Still greater diminution in the congestion of the conjunctiva and in the amount of the discharge. A zinc collyrium was ordered.

August 16th.—Ocular conjunctivæ white; palpebral still congested. Thick yellow masses of the secretion form at the inner canthi—an appearance quite characteristic of this disease. No photophobia, and but slight pain.

August 30th.—Still a very little secretion. Conjunctiva almost normal.

The patient had entirely recovered on September 1st.

Case II.—July 29th.—S. D——, aged seven. Right eye inoculated from a *fourth generation.* The disease ran a course exactly like that in Case I., except that nine days after the inoculation numerous sub-conjunctival hemorrhages in the ocular conjunctiva occurred. The discharge ceased about August 28th.

Case III.—July 29th.—A. S——, aged six. Right eye inoculated, as in the two previous cases, from a *fifth generation.* This case was like the two preceding, except that it was milder. Recovery took place three weeks from the time of the inoculation.

Case IV.—July 29th.—F. F——, aged six. This case was in every respect a repetition of the previous case.

Case V.—September 1st.—M. T——, aged thirteen. The inoculation in this case was made from the *eleventh generation* of the small bacillus. A typical conjunctivitis appeared on the second day, and ran a course as in Case III. of this series, except that on the fifth day a very few marginal phlyctænulæ appeared.

Case VI.—September 1st.—J. A——, aged ten. Right eye inoculated from the *eleventh generation.* The typical conjunctivitis appeared as in Case III., running a somewhat more protracted course.

Preparations of the secretion, for the microscope, were made from time to time. *The bacillus was present in all as long as the yellowish discharge persisted.* Sections of the conjunctiva from three of the cases, obtained by cutting out small portions from the bottom of the lower conjunctival sacs, were examined microscopically after staining by Gram's method. The bacilli, in rather scanty numbers, were found in the anterior layers of the epithelium, either singly or in groups, lying between the cells. Some leucocytes or pus-cells, found in the epithelial layer, showed the bacilli apparently in the interior as well as on the surface of the cells. Cultivation from the secretion from all of these induced cases were made which corresponded in appearance to the original culture.

No corneal complications have occurred in any of the two hundred and fifty to three hundred cases that I have observed. The cornea is affected but seldom if ever in this form of conjunctivitis, unless it is complicated by some intercurrent disease. In Case V. a few phlyctænulæ appeared on the fifth day. This I consider to be the development of a distinctly different disease ingrafted on the older conjunctivitis—an accidental complication. Pyogenic germs, as the staphylococcus, which in the *normal* conjunctival sac are innocuous, and which are probably the cause of phlyctænulæ, undoubtedly find easy entrance to the deeper epithelial layers in the roughened condition of the epithelium due to the former inflammatory action. It will be noticed that in the last six cases described the inflammation in the inoculated eye (O. D. in all) appeared uniformly in about forty-eight hours from the time that the bacilli were introduced. In order to produce this effect there certainly must have been some causative agent in the cultures employed.

Care was taken not to convey any of the original secretion from the first tube to tubes in which the subsequent generations were produced; certainly the fifth, sixth, and eleventh generations were too far removed from the first to admit of the possibility of such an accident. Had it been a simple chemical irritant to the conjunctiva we would have expected to see an immediate inflammatory result, as occurs after the introduction of quick-lime, acids, strong solutions of the nitrate of silver, etc. As it was, no redness of the conjunctiva, no sense of

discomfort, or anything outside of the normal condition was experienced by the patient until thirty-six to forty-eight hours after the inoculation. A period of incubation was necessary to enable the bacilli to multiply sufficiently to produce an inflammatory condition of the mucous membrane.

The researches of numerous observers have demonstrated the fact that quite a large variety of microbes are found in the conjunctival sac. I have myself cultivated four forms of bacilli and six varieties of cocci from conjunctival sacs which were normal or but slightly congested. These, of course, do not include the coccus of Neiser, nor the one recently described by Michel as the causative agent in trachoma. The bacilli of which pure cultures were made were as follows :

1. The clubbed form of which I have spoken.
2. That described by Leber and others as always present in the secretion in xerosis of the conjunctiva.
3. A short, thick bacillus very common in normal conjunctivæ.
4. The bacillus subtilis, or one resembling it very closely.

The following varieties of cocci were found :

1. Staphylococcus pyogenes aureus (Rosenbach).
2. Staphylococcus pyogenes citreus.
3. Staphylococcus pyogenes albus.
4. A large coccus about one and one-half times the diameter of the staphylococcus.
5. One form of the streptococcus.
6. Micrococcus cinnabarens.

The bacilli are met with most frequently in the following order : The short, thick bacillus ; the clubbed bacillus ; Leber's bacillus and the bacillus resembling the bacillus subtilis. The cocci : Staphylococcus aureus, albus, and citreus ; streptococcus, one form ; micrococcus cinnabarens ; the large coccus.

Experiments were made with all of these varieties, except the streptococcus, to show their innocence in producing conjunctivitis by placing small amounts of the pure culture into the normal conjunctival sac. Rabbits were first used, but as no inflammatory result occurred the human conjunctiva was employed. This method of inoculation produced no effect whatever, although tried repeatedly. The different forms were introduced into the corneal tissue and into the anterior chamber of rabbits' eyes, by means of infected instruments and by using the platinum rod. Of the bacilli, Leber's produced an opacity of the cornea in the immediate vicinity of the wound, which cleared up in a few days. The different forms of staphylococcus invariably produced either corneal abcess if introduced into the corneal tissue, or panophthalmitis if well introduced into the anterior chamber. All the other varieties, except the streptococcus, which was not experimented with, were perfectly innocent in wounds of the cornea or when introduced into the anterior chamber.

All of these microbes, except the very small bacillus, grow on ordinary ten per cent. gelatine and on the ordinary agar food preparation.

"In numerous examinations of secretion from the normal conjunctiva and from the conjunctiva in all its phases of disease, I have never met with this small bacillus except in the form of acute conjunctivitis described ; in this disease its occurrence is *constant*." A short time ago Dr. H. Knapp showed me some specimens of microbes, obtained from the deposits about the teeth in one case, and from a corneal ulcer in another, which in form resembled the small bacillus that I have described. No cultivations or experiments to ascertain their character were instituted.

The diagnosis of this disease is not difficult, even without the microscope, if a few cases have been recognized and examined. The discharge is muco-purulent, does not mix with the tears except in very severe cases, and has a tendency to form in light-yellow masses at the inner canthi. The flushing of the ocular conjunctiva, without chemosis or very marked pericorneal injection, is present in its acute stage. There is usually but little photophobia. The absence of marked chemosis and great swelling of the lids is sufficient in most cases to distinguish it from diphtheria and gonorrhœa, but in some cases where a false membrane is present, and in others where the discharge is more puriform, the microscope must be employed to arrive at a correct diagnosis.

The complications that may arise in this form of conjunctivitis are blepharitis ciliaris, phlyctænulæ, false membranes, and possibly trachoma and corneal ulcer—all of which, with the possible exception of the false membrane, being due to the addition of another *germ* factor.

Blepharitis ciliaris makes its appearance, in the cases which it complicates, in from one to three weeks after the commencement of the attack, and sometimes persists long after the original inflammation has subsided. Phlyctænulæ occur in a small proportion of the cases. The false membranes have occurred in six cases that I have observed. In these cases the membrane was quite persistent, lasting in one case more than two weeks ; in another, eight to ten days, etc. They appear in cases where the bacilli are numerous, where proper cleanliness is not observed, and where the hygienic surroundings are bad. The condition is one resembling the so-called croupous conjunctivitis described by Mackenzie, Saemisch, Knapp, Noyes, Manz, and others, and is, I am inclined to believe, identical ; the severity of the cases described by Knapp and Manz probably being due to personal peculiarities, as hyperinosis or cachexia. Papillary excrescences in the fornix conjunctivæ I have not observed, but papillary enlargements, with thickening of the conjunctiva at the fornix, are of frequent occurrence. This disease must not be confounded with the vernal catarrh of Haynes, Walton, Nettleship, and others, the Frühjahrskatarrh of Saemisch and Standke, as it in no way resembles that affection. Relapses are not infrequent, and having once had the affection does not protect the patient from a subsequent attack. The disease may affect the conjunctiva when trachoma or blepharitis ciliaris is present, and possibly when other chronic inflammatory processes are in progress. It runs the usual course in these cases. The trachoma in the three cases that I have watched was much improved when the muco-purulent conjunctivitis had subsided. In one case, that of a nurse who had infected her right eye while cleansing the eyes of a child who was suffering with muco-purulent conjunctivitis, the disease was permitted to run its course, except that the very severe symptoms were modified by making cold applications to the lids. The left eye was treated with sulphate of copper. At the end of five weeks, at which time the acute conjunctivitis had subsided, the infected eye was in much better condition, so far as the trachoma was concerned, than the other ; in fact, the granulations had almost entirely disappeared, while the cornea, which before was quite hazy, became quite clear. It is not improbable that the secretion from this form of conjunctivitis, and cultivations of the bacillus, may become valuable agents in the treatment of trachoma with or without panus, the absence of any tendency to attack the cornea or cause any loss of tissue rendering it a safe agent to employ. Repeated inflammations may be produced at pleasure.

This form of conjunctival disease is most plentiful in the spring and fall months, but isolated cases are met with at all times of the year. It attacks young and old, being more severe in adults than in children.

The observations and experimental results given above, notwithstanding the defect in its cultivation, are, I believe, sufficient to establish the causative effect of the small bacillus in this form of conjunctivitis. The difficulty experienced in cultivating this microbe on artificially prepared food is not unprecedented. Many, in fact the greater number, of known pathogenic varieties are cultivated with difficulty, and some are problematical in this

respect. What the relation is, if any, between the club-shapped and the small bacillus I am not prepared to say. In cultivations that apparently consisted of small bacilli only in the first and second tubes, subsequent inoculations either did not develop or developed in company with the clubbed variety. I do not think that the clubbed variety is a form of the small bacillus in one phase of its development, as I have never observed any transition forms and as I have cultivated the clubbed bacillus from the normal conjunctival sac, the small bacillus, of course, not being present.

"So far as I am aware, no one has heretofore described a microbe as the cause of this form of acute conjunctivitis. Koch (*Wiener Med. Woch.*, 83, p. 1,550), while at Alexandria, Egypt, investigating the cholera epidemic, examined the secretion from fifty cases of conjunctivitis, which included two forms. One of the forms of conjunctivitis, which runs a very severe course, he asserts to be due to the presence of a bacterium which closely resembles the gonococcus and is probably identical with it; the other a very much less severe process, in which a constant condition was the presence of a very small bacillus in the pus-corpuscles. The latter is probably the same form that I have described. Dr. Haensell (*Bulletin Clin. Nat. Oph.*, January and March, 1886, p. 7) mentions having observed a microbe peculiar to acute conjunctivitis, but refrains from describing it, as he has made no cultivations or experiments with it."

In view of the above, and of the ambiguity of the term "catarrhal conjunctivitis," I would suggest the term acute contagious conjunctivitis for this form of disease.

Treatment.—Thorough isolation is the first thing to be resorted to, especially when the disease appears in asylums or residental schools, as it is very contagious. A glance at the long list of remedies advocated by the various writers is enough to show that no specific remedy is recognized. Given a specific cause, we may hope to find a specific remedy. Patients suffering from a disease due to the presence of a germ would probably recover rapidly if a germicidal remedy could be brought in contact with the germ without detriment to the tissue. Usually the germ is so deep in the tissue that applications to the surface cannot reach them; hence the inability to abort gonorrhœa, after the inflammatory stage is well established, by applications of strong solutions of the nitrate of silver, or to stop the progress of diphtheria by the local applications of strong solutions of the bichloride of mercury, although these agents would destroy the specific germs if brought in contact with them. If we cannot reach the germ with a remedy applied to the surface, is it not possible to place the tissue in such a condition that the development of the germ will cease, or be much retarded, without interfering with the vitality of the tissue or with cell-change, sufficient to prevent expulsion of the germ in a comparatively short time? This condition, in many cases, may be produced, I think, by reducing the temperature of the tissue below the point at which the microbe will develop. Many pathogenic microbes require a temperature above 30° C. for their development; this is the case with our small bacillus. If we reduce the temperature of the conjunctiva to 30° or 32° C. we retard the development of the microbe, but do not prevent cell-change. Can this be done? The temperature of the normal conjunctival sac is 97½° F. By *actual experimentation*, I find that the temperature of the conjunctival sac may be reduced to 30° C., providing the lids are but little swollen, by the simple application of iced cloths, and can be easily kept at that temperature without discomfort to the patient. *In the acute stage, cold applications are always grateful to the patient.* Pressure on the lids should be avoided, as this interferes with the vitality of the tissues. The applications should be made with small square pieces of linen, in two or three thicknesses, large enough to cover the lids nicely. Twelve or fifteen of these pieces should be placed on a block of ice and changed to the eye every minute; except frequent cleansing with clean water, to keep the eyes free from the secretion, nothing else is needed for from two to four days. If the applications are made carefully and constantly the acute stage usually subsides in two days. The succulent or lax condition of the conjunctiva, then, requires the use of some mild astringent solution, as of zinc sulphate or the nitrate of silver, applied twice or three times daily.

The above appears to be a rational method for the treatment of this disease, and in practice it proves to be most efficacious.

The average duration of fifty cases by this method of treatment was *two weeks*. In more than one hundred cases where the nitrate of silver solution, one to two per cent., was applied twice daily from the commencement of the discharge, the average duration was about *four weeks*.

Note.—The passages in quotation marks are extracts from a paper published by the writer in the Arch. of Ophthalmology, vol. xv., No. 4, 1886.

MELANOSIS OF THE URINARY TRACT.

By ALEXANDER W. STEIN, M.D.,

VISITING SURGEON OF CHARITY HOSPITAL, NEW YORK.

Melanosis of the bladder is extremely rare in man, and in the few isolated cases, incompletely recorded, other organs were simultaneously involved. The distribution of the pigment in the present case was so general and so extensive as to make it almost unique. It should be noted that this disease is not at all infrequent in some of the domestic animals, notably the horse. In gray and white horses it occurs quite commonly. In them it remains stationary for an indefinite period, and then manifests a disposition to ulceration; but the disease is always tardy in its progress, and I am told the animals rarely, if ever, die in consequence of it. Scarcely anything is known of the clinical features of these deposits, except their tendency to multiplicity, which is remarkable. They have little influence over the vitality and function of the part in which they are found. Where an impairment of function exists, it must, as a rule, be attributed to the causes which have given rise to the formation of the pigment, and not to the deposit itself, unless the latter accumulates in sufficient quantity to interfere, mechanically, with the functional activity of the part, as it not infrequently does in the horse, necessitating removal of the tumor. In the present instance the disease existed in the kidneys, bladder, prostate, corpus spongiosum, corpora cavernosa, and all the principal organs in the body; but how long they were affected it is impossible to say, as the disease did not manifest itself by any symptom during life. About nine months had elapsed from the first external sign until death. Melanotic sarcoma, or carcinoma, are simply growths, with the well-known characteristic structure of these tumors, in which pigment-granules are deposited in such quantity as to make them appear black or brownish-black in color, and this, as in the benignant form of the deposit, is the result of certain changes in the blood-vessels, or in the circulation, in which the coloring matter of the blood escapes and is converted into pigment;

but what these changes are we do not as yet understand. Patients suffering from this disease sometimes pass black colored urine, even when the kidney-substance is not affected.

As in neither of the standard works on diseases of the bladder is there any mention made of this malady, I have transcribed this history, with the autopsy from the hospital records, to which I have added an engraving of the bladder and urethra :

Man, aged thirty-three, German, married, cabinet-maker, vaccinated in infancy. Has several scars, one of them very well marked. Has never had small-pox before, or other exanthematous fever. Cannot say when he was exposed. Has been delirious for some time ; how long cannot be ascertained, nor, consequently, any history of the invasion of the disease. He was brought in on the evening of December 13th, violently delirious, requiring restraint ; he was given two grains of quinine every hour, and slept well after a while, and this morning, the 14th, is apparently entirely rational. There is an eruption, apparently four days old, of thinly scattered small umbilicated vesicles all over the body. Feels pretty well now, appetite good, slightly constipated, tongue a little furred, considerable conjunctivitis, much thirst, but pulse is good. Ordered to grease the face and take two grains of quinine three times a day.

December 17th. — Pretty weak to-day ; pulse, 114. Throat quite sore ; is to gargle with chlorate of potash.

December 18th. — Complains more of throat and tongue, which latter is much ulcerated. Pulse good, but says he feels feeble.

December 20th.—Eruption has run a most rapid and rather incomplete course, and has now dried up. Complains of diarrhœa, which he has had some days, and which was stopped promptly by powders of acid tannic, subnitrate of bismuth, opium, camphor, and creta præparata.

December 21st.—Eruption all gone.

December 22d.—To-day a history was taken of what appears to be a case of melanosis. This eruption began last Easter ; it was first noticed as a little hard knot in the cartilage of the ear, immediately followed by a number of similar knots on the back, and in a little more than a month the whole surface of the body became invaded with innumerable hard lumps of variable size, from that of a duck-shot to that of a large hickory-nut.

These lumps first appear as small knots under the skin, increase in size, approach the surface, become ulcerated, assume an almost black-purple color, with a thin, shining cuticle, and then desquamate ; the scab being moist, leaving at first a moist, purplish surface, and afterward an ordinary red surface, such as that left by any small healing ulcer after the scab has come off, and eventually healing, leaving no scar, only a slight hardness in the integument, to mark its former site. About nine weeks ago the entire skin began to assume a grayish-bronze color and a slightly greasy character. At present there is a horrible, heavy, and altogether indescribable odor emanating from his body. Can't say how long this odor has been about him. In the mouth there is an eruption similar to that on the rest of the body. It has been there about seven weeks. After he came in he had a diarrhœa for six days, but that was controlled by a single dose of bismuth, tannic acid, opium, and chalk. He has no vomiting.

Before this eruption came out he had perfectly good health, but from the beginning of this he began gradually to emaciate and lose strength, and is now much reduced in flesh and power. Seven weeks ago he grew so weak that he had to take to his bed.

He makes no complaint of pain. It is worthy of remark that the small-pox pustules with which he has just been attacked have appeared indiscriminately upon these black papulæ as well as on the sound skin. He says his family who are living are all perfectly healthy, that his father died of dropsy and his mother of cancer of the stomach.

January 12th.—Has been growing steadily weaker for the past three weeks. During the two days past he has been having involuntary evacuation.

January 14th.—Died last night.

Autopsy, thirty-six hours after death. No rigor mortis. Body below medium size, thin, but not extremely emaciated. Color of skin, dark ; upon face and neck, almost olive. Whole surface of body spotted with black tumors, varying from the size of the head of a pin to a half-dollar, generally rounded in shape, projecting perhaps one-eighth inch above surface ; smaller upon upper extremities, smallest upon neck and face, largest upon trunk. These tumors (very small) were to be observed on the conjunctiva ; not upon the scalp, nor in or under the nails. Head : Black tumors in substance and on both surfaces of dura mater, those on the outer surface following course of vessels ; also in falx cerebri. Inner surface of calvarium covered with pigment-spots corresponding to tumors in dura mater. Arachnoid covering convex surface of brain thickened and opaque, generally along course of vessels and in spots ; melanotic tumors in substance of brain generally small, larger upon surface ; also upon surface of lateral ventricles. Thorax : Pleura, both parietal and visceral, studded with small black masses ; also the pericardium. Heart : Weighed fourteen ounces. Walls of left ventricle very thick. External surface covered with pigmented spots, some projecting, some not. In substance of heart the pigment seemed to follow course of muscular fibre. The columnæ carneæ, as well as all the internal surface of the organ, were mottled with the same masses, but not the valves nor the aorta or pulmonary artery. Lungs : Old adhesions on right side ; a few small cicatrices at apex of left lung. Lower lobe of right lung in first stage of pneumonia. Both lungs infiltrated with pigment-matter throughout. Mucous surfaces of larger bronchial tubes containing spots of pigment. Bronchial glands enlarged and black. Diaphragm, containing the melanotic tumors on both surfaces and in substance. Abdomen : The peritoneum, both visceral and parietal, and the omentum and the stomach and the intestines, large and small, and the pancreas and the mesenteric glands, were also invaded and enlarged. Spleen : Six ounces, firm, and dark in color. Liver : Three pounds nine ounces, dark in color, containing many small tumors, especially near surface and in the thin portions ; one large one in the right lobe, size of walnut, extending three-fourths of an inch into substance, softer internally than on surface. Kidneys : Left, three ounces ; right, seven and one-half ounces. Pelvis, especially that of the left, spotted with the little black tumors ; substance, especially the cortical portion, much pigmented ; pyramidal portion comparatively free. Bladder and urethra : Internal surface studded with melanotic tumors (small) ; a few in substance of corpus spongiosum and corpora cavernosa and the prostate. The tumors present also in the testicles and tissues of the cord. The muscles throughout the body, wherever examined (neck, chest, abdomen, back, thigh, lower extremities, etc.), were infiltrated with the same black pigment, which followed, to a marked extent, the course of the muscular bundles. Muscles pale and flabby.

Tracheotomy at the Hamburg General Hospital.—In the year 1886 there were 219 tracheotomies done in the hospital, of which number 151 died, making a mortality rate of about sixty-nine per cent. In January and February of this year there were 48 tracheotomies done for diphtheria, of which number 34 died, a mortality rate of about seventy per cent. ; but it should be mentioned that the endemic of diphtheria which at present prevails here is of a very severe type. The after-treatment of tracheotomies consists in keeping the atmosphere of the room saturated with salicylic acid spray, produced by steam atomizers.—*Cor. Cincinnati Lancet and Clinic.*

Clinical Department.

LOBELIA AS A REMEDY IN ASTHMA.

Dr. J. S. Prettyman, Jr., of Milford, Del., writes: "The result of this isolated case of asthma accords with my past experience in the use of lobelia as a remedy. On April 15th I was called to visit G. W——, aged seventy. Found him exceedingly nervous, supposing himself to be dying. His heart was depressed, and he was struggling for breath, with the sweat rolling from his person. I diagnosed spasmodic asthma and ordered half an ounce of compound tincture of lobelia in half a glass of hot water. There was no occasion for repeating the dose, as he was entirely relieved in fifteen minutes, and slept the rest of the night without recurrence of attack. During his course of lectures four years ago, at the University of Pennsylvania, Dr. H. C. Wood said that this drug (lobelia) was more dangerous than veratrum viride, and advised against its use. To indicate the absurdity of his position, before retiring that night I swallowed and retained half an ounce of the simple tincture in presence of several of my classmates. I slept well and in the morning was in my usual good health. I have frequently used this drug, not only in asthma, but in almost every form of inflammatory and febrile disease, and have yet to meet with a single case of the so called alarming symptoms."

TYPHOID FEVER AND CONTAGION.

Dr. G. W. Robinson, of Trinidad, Col., takes exception to a statement in a recent article by Dr. Benjamin, that typhoid fever can arise only by contagion from a preceding case of the disease. He writes: "Trinidad is located in the foot-hills of the Rocky Mountains, at an elevation of about six thousand feet. Part of the water-supply is obtained from a well on the edge of the river, covered by the sand and gravel of the river-bed. The water is pumped into a reservoir situated on a hill several hundred feet above the town. Another source of supply is a well about a hundred feet from the river, and quite a distance from any houses or out-buildings. There are, in addition, a few wells in the city. The river is a rapid mountain-stream, pure and sweet, except after a hard rain, when it becomes turbid and smells badly. The summer of 1883 was noted for the large number of cases of typhoid fever in Trinidad. I attended three cases in one family. They had used water from a well. About the time that the first case occurred, the river flooded the lower part of the town, and the well was filled with surface water. Other cases seen by me had used water from the water-works, and others again received their supply from the large well above mentioned, lying about a hundred feet from the river. Some lived in the river bottom, and others upon high hills. The water from the reservoir is used only in cases of emergency, the water being usually forced directly into the pipes. At this time it was said that the water from the reservoir and pipes was unclean, and at times tasted and smelled badly, but that from the other public source was, to all appearances, pure and sweet. I would ask how all these different sources could be contaminated with typhoid germs from patients? In November, 1884, I was called thirty-five miles into the country to see a boy who presented a typical case of typhoid fever. There were no other cases in the neighborhood. The water-supply was from a spring gushing out of the mountain-side, the water being carried in troughs for a distance of about a hundred feet. It was cold, clear, and pure. The nearest neighbor was about a quarter of a mile up the cañon. The house was rather open, and there were too many chickens, pigs, dogs, etc., around to render the sanitary arrangements of the best. Two other cases developed in the same family. In July, 1886, I was called to see a girl at a saw-mill camp about forty miles in another direction in the mountains. She was sick with typhoid fever. The water used was from a spring at the bottom of a cañon, about a quarter of a mile from the house. There were no other cases of the disease in the camp or neighborhood, as far as I could learn. From these and other cases I have concluded that, while unsanitary surroundings and the impregnation of water with decomposing material may cause typhoid fever, the germs from a previous case are not necessary to its development. A word about treatment. I am, with Professor Bartholow, a firm believer in iodine and carbolic acid. These and salicylic acid, when the stomach will retain it, with perhaps small doses of aconite and turpentine externally and internally for dry tongue and tympanites, have proved successful in my hands, as in eight years I have not lost a case."

ANTIPYRIN IN DYSMENORRHŒA.

Dr. Z. T. Dellenbaugh, of Cleveland, O., writes: "In your editorial on some of the less common uses of antipyrin, in The Medical Record for February 26, 1887, I do not find any reference to the use of this drug in dysmenorrhœa. Some time in July or August of last year it occurred to me that if antipyrin will relax a hyperæmic and dry skin by virtue of its action on the vaso-motor dilator centres, why will it not relieve an evident hyperæmia of the endometrium? In the first case of painful menstruation to whom I gave it, one of essential and oft-repeated trials with opiates and stimulants of all kinds with their unpleasant sequences. the antipyrin gave immediate and continued relief for that menstrual period, though the patient took but one dose of fifteen grains. Since then I have found that repeated doses of five grains do not afford the relief obtained by an initial dose of fifteen to twenty grains. Whether it will afford the prompt relief in painful menstruation complicated with membranous exfoliation or obstructions I am not prepared to say. I would, however, expect it to, since we occasionally meet with cases of obstruction, flexions, coarctations, and even exudative membranous exfoliations without pain at the menstrual period; an analysis of these, with the cases of essential dysmenorrhœa, inclines one to believe that dysmenorrhœa may, after all, be a neurosis allied to neurasthenia in its various manifestations."

THE HYPNOTIC EFFECTS OF ANTIPYRIN.

Dr. J. Edward Stubbert, of Bloomfield, N. J., writes: "In the editorial columns of The Medical Record of February 26th you refer to the use of antipyrin in cases of hemicrania, and suggest that the hypnotic action is due to 'cessation of pain.' In forty-seven cases of hemicrania I have failed to relieve pain in only one instance, *provided hypnotism was first produced by the drug.* If the attack is fully developed I administer fifteen grains of antipyrin and order the patient to lie down immediately and close the eyes. Sleep comes on rapidly, and in about twenty minutes the patient awakes free from pain. In two cases I was obliged to administer a second dose at the expiration of the first nap because the pain had not fully disappeared, although it was mitigated. In a few other cases, where the remedy was administered during the prodromal stage, no sleep was required, but when the hemicrania is fully developed the hypnotic effect of antipyrin is, I believe, absolutely necessary before relief from pain can be hoped for. In cases of fever, where the drug has been used for its antipyretic properties, I have noticed the same hypnotic action, and here it will be noted no pain is present to be relieved and *thereby* cause sleep. The hypnotic effect is the more marked in proportion to the size of the dose of the drug and the idiosyncrasies of the patient, and I have found that children require proportionately a much larger dose than adults. So confident am I of the hypnotic action of the drug that I at times have successfully substituted it for morphia."

Progress of Medical Science.

Therapeutics of Asthma.—Since the publication of Hack's article suggesting abnormal changes in the turbinated bones as the cause of asthma, specialists and general practitioners have, with the aid of highly magnifying reflectors, seen hypertrophied turbinated bones in many a patient, which there was a great temptation to reduce, either with some ingenious instrument, with the galvanic cautery, or with a powerful escharotic. Although the results have not been so gratifying as Hack's, they have gone far toward affording an appare. t verification of his theory; for, if the so-called hypertrophied turbinated bones could be detected at first only with the aid of magnifying reflectors, it was not long before they were sufficiently hypertrophied to be distinct even to the naked eye. The pendulum, however, is beginning to swing back, as is evident from a recent lively and protracted discussion at several consecutive meetings of the Berlin Medical Society. A number of speakers took part in the discussion, and there seemed to be a consensus of opinion that cases in which asthma was benefited by cauterizing the nasal mucous membrane or the turbinated bones were extremely rare. Such treatment, it was said, should not be employed until a careful examination had been made with a sound, the parts having been made anæsthetic with cocaine, and an area discovered a touch upon which would call forth an attack. Schadewald broached a novel method of treatment, based on his no less novel theory of the pathology of the disease. He maintained that bronchial, or true asthma was due to a neurosis of the trigeminal nerves, and should be treated by faradization of those nerves, the applications being made during an attack, as if made in the intervals they would call forth a paroxysm. Lublinski emphasized his previous remarks as to the benefit to be derived from inhalations of pyridine, but the drug must be used with caution, as disagreeable and alarming symptoms may follow its injudicious use. Amyl nitrite nitro-glycerine, and sodium nitrite act in the same way as pyridine, but all these remedies find their more appropriate application in cardiac asthma. If any drug deserves the title of a specific in this affection, it is potassium iodide. The remedy was first recommended in asthma by Trousseau, but this use of it fell into oblivion for a number of years, to be only recently restored by the publications of Leyden and Germain See, the latter of whom recommends its administration with lactucarium. Potassium iodide is of great service also in the purulent bronchitis which occurs as a sequel to asthma. In many cases of this condition the various balsams are efficacious, and Lublinski has observed excellent results from the use of the Peruvian balsam combined with myrrh, the former in doses of from a grain and a half to three grains three or four times a day. If there is really a nasal affection, it should be treated according to its character, and not on any far-fetched theory of its etiological importance. But, in the treatment of asthma, it is of the greatest moment to distinguish true, or primary, asthma—by no means a common affection—from that which is secondary to disease of the heart or lungs. We need scarcely say that we have had only the former in view in this writing.—*New York Medical Journal.*

Tonsillitis and its Relations to Scarlatina and Diphtheria.—Dr. Hingston Fox sums up his conclusions on this subject as follows: 1. There is a commonly occurring form of tonsillitis, symmetrical, varying much in severity, distinct from suppurative quinsy, due to septic causes, often attacking several members of one household, and frequently prevalent at the same time as scarlatina and diphtheria. 2. Short-lived outbreaks of so-called infectious sore throat occur, associated with unsanitary conditions, the cases often varying much from one another, but intermediate in their general characters between tonsillitis and the two specific fevers. 3. The throat lesion is the symptom most constantly present in both scarlatina and diphtheria, but its degree and character very greatly vary; it is in some cases apparently identical in nature in the two fevers; and it may be absolutely indistinguishable from the common form of tonsillitis first alluded to. 4. There is some reason for regarding scarlatina and diphtheria as essentially forms of tonsillitis which have acquired the power of infecting the system generally. 5. The virus of these two fevers may probably enter the lymphatic system through the tonsil, producing tonsillitis as a primary effect. 6. The specific character of these diseases is connected with the power of the poison-germ to overcome the resistance of the tissues so far as to reproduce itself in the human body without deterioration; a certain series of lesions is thus set up before the poison is destroyed, and in the meantime its multiplication affords a supply of *contagia* for the communication of the disease. 7. This power of withstanding the resistance of the tissues and reproducing itself within the human body has probably been acquired under a process of evolution. 8. There is nothing in the occurrence of scarlatina and diphtheria of wounds, and of other mucous surfaces than the fauces, to contravene the hypothesis that the poisons of these diseases in ordinary cases enter at the tonsils. 9. The tonsils are absorbent glands, and their function may not improbably be connected with the absorption of certain elements from the saliva.

The Reciprocal Influence of Diabetes upon Syphilis.—The question of the connection between diabetes and syphilis is of recent date. Different authors have only kept in view the fact of syphilis being regarded as the cause of diabetes, and have paid but little attention to diabetes coexisting with syphilis. It is the latter point which gives great interest to the recent thesis of M. Arnaud. Two circumstances may arise where diabetes and syphilis are coexistent: (1) The patient may have been suffering from diabetes for a longer or shorter period when he contracts syphilis, and the latter complaint is modified in its evolution and progress from the fact of diabetes having preceded it; (2) diabetes developing after syphilis seems to be the direct or indirect consequence of that disease. The result of M. Arnaud's observations on this subject have led him to the following conclusions: When diabetes has pre-existed, it modifies the clinical aspect of syphilis, either because it induces cachexia, and thus renders the patient less able to resist the invasion of the disease, or because it exercises an injurious influence upon the anatomical elements by bringing them into direct contact with the sugar contained in the pathological secretions of the human economy. It cannot be denied that syphilis may give rise to diabetes, which may be more or less persistent, owing to the changes in the blood and tissues which it constantly produces. Syphilis may bring on another form of diabetes through tertiary products (gummata) becoming developed in the surrounding parts of the fourth ventricle, and compressing the centre of glycosuria described by Claude Bernard. When syphilis develops in a diabetic patient, infective chancre and secondary lesions have a tendency to ulcerate. As these deviate from their ordinary aspect, they may give rise to an error in diagnosis. Under these circumstances, the evolution of syphilis appears more rapid than in a normal case of the complaint. According to some writers, sugar disappears when specific symptoms show themselves. M. Arnaud's observations prove that sugar seems to leave the urine more rapidly in these cases than in ordinary diabetes. Syphilis will prove more serious in diabetic patients than in others. Anti-diabetic should be combined with anti-syphilitic treatment in such cases.—*British Med. Jour.*

The Late Sir Thomas Watson received, for many years, $1,000 annually from the sales of his book.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 21, 1887.

THE CAUSE OF THE RHYTHMICAL CONTRACTION OF THE HEART.

THERE have been two opinions held by physiologists concerning the mechanism of the rhythmical pulsations of the heart. Some have held that the beats succeed each other regularly by muscular action simply, without the intervention of the nervous system, at least as far as the rhythmical action is concerned. Others, and the majority, believe that the rhythm is under nervous control. But as the heart of a frog, for instance, will continue to beat for some time after its removal from the body, and consequently after all connection with the central nervous system has been severed, the regulating ganglia are supposed to reside in the substance of the heart itself. These ganglia, the most important of which are situated in the sinus, are not supposed to originate the cardiac pulsations, but simply to regulate them and give to them that character of rhythmical succession which is so characteristic of the cardiac muscular movements. Two German physiologists, Kronecker and Schmey, claim to have located the co-ordinating centre, in the heart of the dog, at the point of union of the upper and middle thirds of the anterior interventricular sinus.

Some experiments recently undertaken by MM. Germain Sée and E. Gley, and reported by them to the Academy of Sciences of Paris, seem in a measure to confirm these views. The experiments were made on curarized dogs, the two vago-sympathetic nerves being sometimes divided and sometimes left intact, artificial respiration being maintained, of course, during the continuance of the experiments.

A needle being thrust into the heart at the point indicated by the two physiologists above mentioned, there ensued immediately very energetic contractions of the ventricles, which were, however, wholly irregular, rapidly becoming weaker, and finally degenerating into mere tremulous oscillations. These soon ceased, and the ventricles became fully dilated, while the auricles continued to beat rhythmically. As soon as these trembling movements became established, the arterial pulse disappeared, the arterial blood-pressure fell to zero, and it was impossible to re-establish the ventricular movements. This effect was observed but three times out of fourteen experiments, a fact which the authors regarded as showing that this anatomical centre is either indefinitely located as yet, or else that it is very limited in its area.

Trial was then made of electrical stimulation of this supposed co-ordinating centre. Faradization of this point by a current of moderate intensity caused tremulous movements of the ventricles, and it made no difference in this respect whether the pneumogastric nerves had previously been paralyzed by atropine or divided, or left intact. These results were obtained not only after electrization of the upper third of the interventricular sinus, but also when the stimulus was applied to the middle and lower thirds, or even to any part of the ventricular walls.

These results, the authors thought, were not conclusive as to the existence of a co-ordinating centre for the muscular movements of the heart. The fact that a lesion of the heart at the point above indicated excited ataxic movements of the ventricular walls could not be gainsaid, and this would plainly point to the presence of a group of nerve-cells in this situation. But the question that still remained unsolved was the functional nature of this centre. It was possible that stimulation of this group of cells might excite such violent contractions of the cardiac muscle as speedily to destroy its irritability, so that it was incapable of recovering its normal function.

These researches may have a practical bearing in a strictly medical point of view, for, according to M. Sée, angina pectoris is due to the obliteration of the nutrient arteries of the heart-wall. He has also demonstrated that the injection of an inert powder into the coronary arteries, or the ligature of one of them, is followed by tremulous movements, apparently identical with those excited by electrical stimulation or injury with a needle. It is therefore allowable to assume, they conclude, that irritation of this collection of cells, following obliteration of a coronary artery, may transform the ventricular contractions, already disturbed, into the above-described oscillations, quickly becoming fatal.

However this may be, it seems reasonable to believe with the authors that much light may be thrown in the future upon the mechanism of angina pectoris by a careful study and increased knowledge of all the facts relating to this vital ganglion or group of nerve-cells lying in the interventricular sinus.

BEQUESTS AND DONATIONS TO THE NEW YORK ACADEMY OF MEDICINE.

AT the stated meeting of the Academy on May 5th the Treasurer for the Trustees reported the following munificent additions to the permanent funds:

1. From Henry S. Rokenbaugh, Esq., executor of the estate of Mrs. Celine B. Hosack (widow of the late Dr. Alexander E. Hosack, formerly of New York), the sum of $70,000, upon the following conditions, as expressed in the testatrix's will:

"Third: I estimate the total value of all the property which I acquired from the estate of my lamented husband as not exceeding the principal sum of seventy thousand dollars, and I do give and devise and bequeath unto the society or corporation known as 'The New York Academy of Medicine' the sum of seventy thousand dollars, payable within one year after my decease, which it is my

will and desire shall be devoted or applied by the board of trustees of the said society or corporation to the purchase or erection of a library building or lecture-room, or some other suitable building adapted to the purposes of said society, which, in memory of my dear husband, Alexander E. Hosack, shall in some appropriate manner be designated with and known by his name forever.

"If the said sum of seventy thousand dollars shall be insufficient to defray the entire expense of constructing the whole of any building, to the erection of which the board of trustees of the said society may deem it proper to apply the money, then it shall either be allowed to accumulate at interest until the amount shall be sufficient for the purpose, or it may be used and applied to the construction of any separate part of the building, or any particular room or suite of rooms, or any wing or addition to any building belonging to the society, and devoted to the objects for which the said society was incorporated, which can be separately distinguished from the other parts of the same building so as to be dedicated and designated in some suitable manner as a monument in memory of my husband."

2. From the same source, a free bed in perpetuity in the Roosevelt Hospital, as follows:

"Eighth: I do give and bequeath unto my executors hereinafter named, the sum of ten thousand dollars, in trust, to apply and pay the same (or so much thereof as may be necessary) to 'The Roosevelt Hospital' in the city of New York, to purchase a bed which, in memory of my husband, shall be known as the Hosack bed, and which shall be occupied from time to time by such sick and needy physicians as may for that purpose be named or designated by the President and Treasurer for the time being of the New York Academy of Medicine."

3. Through the President of the Academy, Dr. A. Jacobi, the donation of $5,000, largely due to the generosity of Mr. Jacob Meyer, of New York, upon the following conditions:

1. "The fund is to be forever known as 'The Philippine Meyer and Ernst Jacobi Library Fund,' and be so borne and described in the accounts of the New York Academy of Medicine and in any publication by the Academy enumerating the several trust-funds in its possession."

2. "The income from the fund to be applied to the purchase of books for the reference library. Each book so purchased to be appropriately marked and designated so as to indicate that it is the proceed of this fund."

3. "It is also covenanted and agreed that the existence of this fund shall in no way affect the appropriation of such other moneys or funds as the Academy may find desirable for the acquisition of journals or other books."

THE DOCTOR'S SUMMER PRACTICE.

The approach of the summer months brings to physicians reminders of the great change which has occurred in the course of medical practice during the past fifteen years. In this time there has been a constant development of, and increase in, the custom of moving to the country or seaside for the summer, so that now in cities all the wealthy families and a majority of those of moderate means leave their homes for three or four months in the year.

The result is that the general practitioner in the city often finds himself almost without paying patients when the hot weather comes on. And it has come to this, that many physicians have to earn their living for the year during the fall, winter, and spring months.

The exodus of citizens from the cities in summer is bound to continue, for it is a practice based on good sense and good hygiene; therefore the wise physician will lay his plans accordingly. If the patient goes out of town, the doctor should go also. He should select some locality agreeable to himself and family, make it his summer home, and attend with diligence and skill to the physical ills of the exiles about him. By judicious continuance in such a course he will find that he can spend his summers pleasantly and with little expenditure of the hard earnings of the winter.

The charges made against the city doctor at summer resorts is that he is extortionate in price, and that he interferes with the practice of local physicians. These are, perhaps, true as regards a few of our profession who have the hard-headedness, the fine business instincts, and the advanced ideas in economics so much admired by some; but, on the whole, we incline to the hope that the vacation practice of the city doctor is conducted very honestly, and to the benefit of his fellow-men. But, at any rate, the physician who looks ahead will, if he is wise, so arrange his affairs that he can do a little work in the summer and make all the twelve months of the year contribute to his support.

RECENT VIEWS OF THE PATHOLOGY OF THE RENAL TROUBLES OF PREGNANCY.

At a meeting of the Berlin Medical Society, not long ago, Professor Leyden read a paper upon dropsy and albuminuria in pregnancy. His contribution to the subject was one tending mainly to show how diverse are the present ideas as to the pathology of these disturbances. Renal disease in pregnancy is, according to Leyden, a form of disease caused solely by "the conditions of pregnancy," and diagnosticated by the fact that it begins in the second half of a first pregnancy chiefly, and progresses steadily until parturition occurs, when it generally disappears.

The anatomical appearances of the kidney have been found to vary greatly, from that of acute parenchymatous nephritis to that of congestion or anæmia. Leyden holds that the condition is one resulting from long-continued arterial anæmia.

Dr. A. F. A. King (*American Journal of Obstetrics*, March and April, 1887) has advanced "A New Explanation of the Renal Troubles, Eclampsia, and other Pathological Phenomena of Pregnancy and Labor." Dr. King's views evince originality and ingenuity, and they are presented in the attractive and logical style characteristic of this distinguished obstetrician.

Professor King's idea, in brief, is that the renal and other troubles referred to are brought about by the uterus not keeping above the pelvic brim—as it ought to do—until the time of labor is reached. The normal position of the pregnant uterus and fœtus is one of lateral obliquity, the head generally lying on one iliac fossa. If, for any reason, the womb stands vertically, then the head or breech presses down upon the renal and iliac vessels.

It is very evident that if this theory is true there should be no eclampsia or albuminuria with transverse presentations, except from extrinsic causes. Professor King has industriously collected a large number of facts bearing upon this point.

Thus, he states that Schanta, who had 315 cases of eclampsia in 134,345 deliveries at the Vienna Hospital, found the head to present 304 times; face, 4; breech, 5; foot, 1; and transverse, 1. In 306 of these cases, 253 were primiparæ. From an analysis of Rambotham's 59 cases of eclampsia, it is fair to assume that there was not one of transverse presentation. Of the 14 cases in 7,404 deliveries in Guy's Hospital Lying-in Charity there were 13 head presentations and no transverse. In a total of 300,018 labor cases collected by Dr. King, with 212 cases of eclampsia, there is only one distinctly isolated coincident occurrence of eclampsia and transverse presentation during labor; and in regard to this case there is no detailed account.

Dr. King's views have a distinct practical outcome, for he states that disturbance of the normal lateral obliquity of the womb and child, with consequent descent below the pelvic brim, is caused by tight and ill-fitting dresses, corsets, coitus, and certain abnormal postures, all of which things can be measurably prevented.

MARTINEAU'S TREATMENT OF DIABETES.

In a recent issue of The Medical Record we referred briefly to the plan adopted by M. Martineau in the treatment of glycosuria. The results obtained by this method, as reported by the author, are, to say the least, remarkable. And, in view of the large number of cases, the length of time that the patients were under observation, and the professional standing and credibility of the reporter, the method would seem to call for a more extended notice than it has hitherto received.

The plan was adopted by M. Martineau, at the instance of Dr. Rouget, some twelve years ago, and in seventy cases in which it has been employed since 1875, a cure of the disease has been obtained in sixty-seven, or nearly ninety-six per cent. The method, which is simple enough, is described by the author in a paper read by him at a meeting of the Société d'Hydrologie, and published in the *Annales Médico-Chirurgicales* for March, 1887. The patient is not obliged to modify his diet to any great extent, except that he is, of course, advised to abstain, as far as possible, from starchy foods, fruits, and sugar. Instead of the ordinary beverages at meals he is to drink a solution of carbonate of lithia and arseniate of soda. A paper containing twenty centigrams (three grains) of carbonate of lithia and a tablespoonful of a solution of arseniate of soda, twenty centigrams to five hundred grams (three grains to the pint) of distilled water, are put in a syphon-bottle holding about a litre (two pints) of aërated water. The patient uses this water as his only beverage, drinking it with his meals and at any other time when he is thirsty. At meal-time, however, it may be taken mixed with wine, if the patient so desire. This is the whole treatment, and no other drugs are given, except for intercurrent troubles which may arise independent of the original malady.

The author reports several cases *in extenso*, one of which, the first, we will reproduce in brief to show the rapidity with which the sugar disappeared from the urine.

The patient was a man sixty years of age, who had suffered from glycosuria for five or six years. In September, when the treatment was begun, he was passing one hundred and twenty-three ounces of urine in the twenty-four hours, which contained three thousand one hundred and eighty grains, or over six and a half ounces, of sugar. Three weeks after the commencement of treatment he was passing seventy ounces of urine and six hundred grains of sugar. In December, three months after the patient first began treatment, he was passing but thirty-five ounces of urine, which contained three hundred and five grains of sugar. From this time until the patient's death, four years later, analyses of the urine were made every month, but no trace of sugar was found at any time.

This method, the author is led by his experience to believe, is efficacious only in those cases of diabetes occurring in individuals of a gouty or rheumatic diathesis. In the three cases in which no benefit was observed the patients presented no evidences of an arthritic tendency.

M. Martineau has shown a commendable degree of patience in thus waiting twelve years before giving his method to the world. But, as he says, this was because he desired to test it thoroughly, and to satisfy himself that it was really of value, before making for it any claims which later trials would show to be not borne out by the facts. He now, however, makes positive claims for this plan of treatment, and the confidence with which he asserts its efficacy in suitable cases will doubtless induce many others to make trial of the same remedies, with what results the future will show.

THE NECESSITY OF EXAMINING THE MOUTH BEFORE GIVING AN ANÆSTHETIC.

It may seem superfluous to repeat a caution which is contained in every text-book on minor surgery, but one is apt at times to grow a little careless, and to forget small details when the mind is occupied with anxious thoughts. When an operator has so many assistants that one can give his undivided attention to the administration of the anæsthetic, as should always be the case where possible, any omission of such details is, of course, inexcusable. But it often happens, in cases of emergency, that the assistant must not only give the anæsthetic, but also assist the operator in many other ways. He is then liable to forget the possibility that something may be in the mouth which is not unlikely, when anæsthesia is complete, to become loosened and fall back into the air-passages. It may be that the patient has a false tooth, or several false teeth attached to a plate, or a palate obturator, or some other apparatus to supply a deficiency in some part of the jaw. Children are very apt to have marbles, lumps of sugar, pieces of cake or candy, or the like, which some fond relative has given them to help them to bear the approaching ordeal with greater courage. Any one of these objects is liable to be drawn into the larynx when all the muscles are relaxed and reflex movements abolished, and when the patient is taking deep inspirations.

An accident of this nature is related by Dr. Trossart in a recent number of the *Lyon Médical*. The patient was

observed to be vomiting almost continuously at the commencement of anæsthesia, and afterward, when the head was turned over, a plate, with four teeth attached, fell out of the mouth. The object in this case was so large that it could not enter the larynx, but was drawn into the pharynx, and excited reflex efforts to vomit. Had it passed farther down, and become lodged in the œsophagus, the results might have been far from trivial.

Similar accidents have happened more than once, and a repetition of this caution would seem, therefore, to be worth the while. The cautious and those who always have their wits about them will pardon the repetition for the sake of their brethren with weaker memories. Always, as a matter of routine, examine the mouth of every patient before commencing to administer an anæsthetic. A neglect of this apparently trifling detail may cost a life.

THE NOMINATION OF A HEALTH OFFICER OF THE PORT

The nomination again made by Governor Hill, of Dr. Charles Phelps for Health Officer of the Port, excites the most general and hearty approval. The recent investigation regarding the disinfection of rags has rather, whether justly or not, cast a cloud over the present health officer. His term has expired, and a new appointment is in order. Dr. Phelps is a gentleman widely esteemed and widely known; and it would be gratifying to the profession of this city to have one of its own distinguished members elevated to such an important trust.

THE QUESTION OF THE COMPENSATION OF EXPERTS AGAIN.

In 1875 the Supreme Court of Alabama confirmed a fine imposed upon a physician who had refused to give expert surgical testimony on the ground that he had not been remunerated therefor. In 1879 the Court of Appeals of Texas held a somewhat similar doctrine, viz., that a medical expert could be compelled by the Court to testify as to the results obtained by a post mortem examination. The law of Indiana (Rev. Stat., 1881, p. 94) is that experts may be compelled to appear and testify to opinions without payment other than that allowed to ordinary witnesses. The action of a certain Ohio court and the unfavorable state of affairs in New Mexico and Dakota has been set forth in The Medical Record of January 8th and February 5th.

It must have been from experiencing the hardships of decisions which prevail in Alabama, Texas, and Ohio that leads a correspondent to write a most emphatic protest against the decisions of judges who do not allow extra compensation for medical experts, and leads him to suggest the bringing out of a test case.

In our opinion, however, a test case is not needed. The majority of decisions, and in many States the law itself, favors the view that medical men should be adequately compensated for giving expert testimony. Indeed, in the present state of the matter it can be only ignorant or grossly partisan judges who refuse to allow such compensation, except, of course, in the States or Territories in which a law, like that passed by the stupid legislators of Indiana, exists.

News of the Week.

The Second Annual Meeting of the Association of American Physicians will be held in the Army Museum building at Washington, D. C., June 2 and 3, 1887.

New York Pathological Society.—The meetings of this Society will be held hereafter, beginning Wednesday evening, May 25, 1887, at the New York Polyclinic, 214–216 East Thirty-fourth Street.

The Ninth Annual Congress of the American Laryngological Association will be held in the hall of the Academy of Medicine, New York, May 26th, 27th, and 28th. The profession is cordially invited to attend.

The New Hospital at Poughkeepsie.—The following gentlemen of New York City have been appointed the consulting board of the Vassar Brothers' Hospital at Poughkeepsie: *Consulting Physicians*—Drs. Fordyce Barker, A. L. Loomis, and J. H. Douglas; *Consulting Surgeons*—Drs. George F. Shrady, T. M. Markoe, and E. L. Keyes.

New York Academy of Medicine and the late Dr. E. Darwin Hudson.—The Section in Practice met at the Academy, Tuesday evening, the 17th inst., and was called to order by the President, Dr. A. Jacobi, who spoke of the great loss sustained by the death of the Chairman, Dr. E. Darwin Hudson. The Section then elected Dr. Charles L. Dana Chairman, to fill the unexpired portion of the term. On motion by Dr. T. H. Burchard, a committee was appointed to prepare appropriate resolutions on the death of Dr. Hudson, to be reported at the next meeting of the Academy. The Section, as a mark of respect to the memory of its deceased Chairman, then adjourned.

Anæsthesia of the Anterior Two-thirds of the Neck can be produced by making an incision, even a very slight one, in the skin in the neighborhood of the larynx. Laryngotomy, thyrotomy, and cutting the throat ought to be performed almost painlessly therefore. Such are the conclusions reached by the experiments of Dr Brown-Séquard.

Women and their Odors.—Hysterical women under sexual or other excitement exhale an agreeable odor, say several eminent neurologists. A French writer goes further and says that in early youth many women exhale a perfume whose entrancement extends even to the clothes they have cast aside for the wash. Again, "in general hospitals one is never deceived, the female wards smell of butylic acid." With all due respect to distinguished experts in olfaction, it appears necessary to say that the foregoing is more or less preposterous nonsense. Female wards do not smell of butylic acid, and the perfume which extends to the clothes that have been given to the wash is more liable to be perspiratory, axillary, and leucorrhœic than an entracing emanation from Araby the Blest. Those who have observed an agreeable odor in women under sexual excitement are liable to the accusation of suffering from subjective disturbances at the time.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 5, 1887.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. F. A. CASTLE, Treasurer of the Trustees, reported that the Academy had received, from the estate of Mrs. Celine B. Hosack, widow of the late Dr. Alexander E. Hosack, the sum of

SEVENTY THOUSAND DOLLARS.

That Mrs. Hosack had also given *ten thousand dollars*, for a *free bed* in honor of her husband, in Roosevelt Hospital, to be occupied by such sick and needy physicians as may for that purpose be named or designated by the President and the Treasurer of the Academy. The Treasurer further reported that the Academy had received, as a special library fund, the sum of *five thousand dollars*, to be known as

THE PHILIPPINE-MEYER AND ERNST-JACOBI LIBRARY FUND,

the income from which was to be spent annually in the purchase of books for the library.

DR. P. A. MORROW then read a

MEMOIR OF H. P. FARNHAM, M.D.,

which was a fitting tribute to the memory of a most worthy man.

THE ULTIMATE RESULTS OF THE MECHANICAL TREATMENT OF HIP-JOINT DISEASE.

DR. NEWTON M. SHAFFER read a paper on the above subject, in which he gave an analysis of fifty-one cases occurring in the service of the New York Orthopædic Dispensary and Hospital. In the performance of the work necessary to the ascertaining of the results he had been largely aided by Dr. Robert W. Lovett, of Boston, Mass. The principal object of the writers of the paper had been to arrive at *the ultimate results* of mechanical treatment of the disease in *dispensary* cases, where facilities existed for making and modifying the instruments and a competent corps of surgeons were in attendance. He then spoke of the difficulties in managing chronic dispensary cases, and also of the fact, which none would deny, that better results could be obtained in private practice. One of the objects of the paper was to demonstrate that it was not only possible, but

COMPARATIVELY EASY,

to treat hip-joint disease successfully and satisfactorily with the means offered by a well-equipped dispensary. To be sure, there were many cases which required hospital facilities, but there were very many bad cases which could be cured by dispensary treatment, with an occasional visit in addition to the general supervision of the surgeon. Dispensary treatment meant an interested parent or friend who would carry out the directions of the supervising surgeon.

THE OBJECTS AIMED AT IN TREATMENT

had been (1) to overcome, by mechanical means, any acquired deformity which existed before treatment was commenced; (2) to protect the diseased joint from traumatism; (3) to permit the patient to have an almost unlimited amount of out-of-door life; (4) to maintain that position of the limb which would reduce the deformity to the minimum, and at the same time favor locomotion when anchylosis occurred.

Abscesses, as a rule, were not interfered with. They did best when allowed to open spontaneously. As a matter of necessity, little or no medication could be employed in the treatment under these circumstances. The mechanical treatment consisted in the use of the long hip-splint, without a joint, from beginning to end. An intermediate splint would be used sometimes in the course of treatment in private practice.

Of the 51 cases, the histories of which *could be traced*, death occurred in 4, but after the lapse of several years from the date of their discharge from the dispensary. Six patients had relapses; they had been under treatment two, two and one-half, four, four, five, and seven years, respectively, and from two to five years passed before the relapse occurred.

Of the remaining 41 cases, 3 were reported well, but they could not be examined. The remaining 38 patients were examined carefully. They were under treatment from two to eight years. Eighteen were cured before ten years of age, with more or less of shortening, and not less than an inch of atrophy of the limb. In 19 cases there was practically anchylosis. In 3 cases there was

FREE MOTION IN EVERY DIRECTION.

Of these there was abscess in two, and no abscess in the other. But the amount of motion *grows less* as time passes.

As to the position of the limb, *adduction* was a very serious ultimate result. In only one case, notwithstanding the shortening of the limb, was there true lateral rotary curvature of the spine. The amount of shortening does not depend upon abscess. The muscular atrophy never entirely disappears.

Conclusions.—The authors of this paper concluded, *first*, that the conservative method of treatment promised better ultimate results than exsection of the hip-joint; *second*, that of the 51 patients discharged cured, 4 died, 2 presumably of tubercular disease, and 2 of acute affections; 6 relapsed, and of these 2 had been cured the second time, and 2 were under treatment; *third*, of the 41 who recovered no one had been incapacitated for doing a full day's work, and none of these had given any evidence of tubercular disease.

Dr. Robert W. Lovett, of Boston, did the work of measuring and otherwise examining the patients at their homes, and he found them to be of the average of dispensary cases. They were exceptionally healthy people, having recovered from their hip-joint disease. Only a few wore high-soled shoes on the affected side. Adduction was the most important deformity. A good deal of shortening with flexion was carried without serious inconvenience, whereas only a slight amount of adduction gave rise to marked impediment in locomotion.

DR. J. F. RIDLON believed it had been proved that dispensary patients with hip-joint disease could be treated successfully. It had been assumed that all these cases were tubercular in character, but he believed there were cases which were due to traumatism, and also to inherited syphilis. These facts should modify treatment. In a case due to traumatism, he thought it was good surgery to remove the dead bone, as was done when death of the bone occurred elsewhere. And he also believed that surgical interference could save the life of some patients which would be destroyed by the disease, treated only by mechanical means. If due to syphilis, anti-syphilitic measures should be adopted in addition to the splint, and he had seen syphilitic cases

RECOVER WITHOUT THE SPLINT

under anti-syphilitic treatment. In dispensary cases and tubercular patients, he thought that some gain could be obtained by the use of internal remedies in addition to mechanical means.

DR. S. KETCH said, while at the New York Orthopædic Dispensary and Hospital it was held that, in the majority of cases, the tubercular diathesis was present, such was not the absolute doctrine of the institution. Besides, it could be said, he thought, truthfully that a great many of the patients who came there received considerable internal treatment, such as cod-liver oil, etc. His personal experience with mechanical treatment had led him to believe that it was the most satisfactory method of

treating hip-joint disease. It was not only the ultimate result which made mechanical treatment so satisfactory, but it were quite as much the present relief which could be afforded by it. He believed that many of these patients were saved from the knife by means of mechanical treatment.

Dr. Lewis A. Sayre believed that, if mechanical treatment were properly applied, recovery could be expected in nearly all cases, whatever might be the predisposing cause. So far as his experience went, in almost all cases

SOME EXCITING CAUSE HAD DEVELOPED THE HIP-JOINT DISEASE,

and it could be traced to some injury. "A thousand and one" little injuries might start the trouble in a child that had some constitutional taint, whereas in a robust, healthy child no trouble whatever would follow these little thumps and bruises. And by recognizing the disease early and treating it with mechanical appliances, a cure could be effected in the great majority of cases, and also, as he thought, with much better motion than had been secured in the cases reported by Dr. Shaffer in his valuable paper. He knew of scores of patients who had recovered, with excellent motion.

But in some cases the peculiar constitutional condition of the patient prevented the disease from yielding to this method of treatment, and then the knife should be used. If under local and constitutional treatment the case progresses favorably, do not resort to the knife; but if, notwithstanding this, the disease progresses, he would, instead of allowing it to go on for six or eight years,

PERFORM EXSECTION

and remove the dead bone. So far as ultimate results were concerned, after exsection, there was no question. His own cases, taking the list as a whole, had not yielded as satisfactory results as could be obtained, because the operation had been performed in the very worst cases, many times in opposition to the opinions of other surgeons, and in cases in which the patients had been given up to die. In some of these cases, however, the final result had been as nearly perfect as it could be, and motion had been better than it was in the opposite

Dr. V. P. Gibney had been interested in the paper, because heretofore but little had been known concerning hip.

the ultimate results of mechanical treatment. There were two points that had interested him especially, namely: (1) The ultimate result with reference to motion, and (2) the ultimate result as to atrophy. It seemed to be proved by the paper that motion would *diminish* instead of increase as time went on, and that a certain amount of atrophy was permanent. Both of these results were important.

His facilities for observing mechanical treatment had not been very good until within a few years, and during that time he had not allowed an opportunity to pass without putting it to the practical test.

Dr. Sayre.—Thank God.

Dr. Gibney continued that, so far as his experience went, the immediate results had been most gratifying with regard to affording relief from pain, and the general comfort the mechanical treatment afforded the patient. Notwithstanding all these good results, both immediate and ultimate, he believed that

MUCH WAS YET TO BE LEARNED ABOUT THE METHOD.

Dr. A. B. Judson appreciated the fact that adduction was the most troublesome feature of the deformity attending hip-disease. Walking with an adducted limb was attended with a characteristic spasmodic lordosis at every step, and another striking peculiarity was found in the fact that the natural rhythm of the gait was destroyed.

Now, if the patient can be induced to restore

THE NATURAL RHYTHM OF THE GAIT

and to divide the time spent on the ground equally between the two feet, he will gradually and unconsciously substitute abduction for adduction in order to place the affected limb and the splint in the most favorable position for doing their share of the work of progression. It was his rule of practice to require the patients to observe the natural rhythm of the gait. He believed that adduction had been thus prevented and reduced.

Some children have a natural excellence in walking. They will easily balance themselves on the hip-splint when sitting on the perineal strap, and secure grace by giving the well limb ample time to take its step forward. Such patients will escape adduction. So will a child who, through parental watchfulness, has acquired the habit of walking with as much grace as the hip-splint allows; but the awkward and unrestrained lad will have adduction.

He was also of the opinion that after recovery the patient should persistently cultivate the natural rhythm of the feet, and that advantage should be taken of the dancing school and military drill, not only to assist the recovered patient to bear gracefully existing disability, but also to reduce or prevent the occurrence of adduction.

Dr. H. Ling Taylor regarded adduction as the most important deformity, but he thought it was due to the fact that patients shrank from putting their entire weight upon the perineal band. He believed that in private practice adduction could be overcome in every case; for he would then use, in the later stages of treatment, the jointed splint, which gave better results than the long splint alone, and would also use

THE ADDUCTION CRUTCH,

which transferred the pressure to the opposite groin, a piece of accessary apparatus that had superseded entirely the adduction screw. He would further remark that the patients who were so long under treatment were not necessarily doing badly, but they were retained under observation and treatment as seemed necessary.

Dr. L. H. Sayre thought that great credit was due to the authors of the paper and to the institution of which Dr. Shaffer had charge, as the results were very much better than anyone would have expected twenty years ago. He was pleased to hear Drs. Gibney and Taylor express their favorable opinions of mechanical treatment. By length of time, mentioned by his father and referred to by Dr. Taylor, he understood that it had reference to cases which were not progressing favorably, and in such cases he believed that it was better to exsect rather than to wait for the bone to exfoliate by the natural processes of the disease, which might require six or eight or more years, with the danger of involving the liver, kidneys, etc. After the operation, give the patient the benefit of mechanical treatment. At the same time he would not advise

EARLY EXSECTION,

as he believed that the results would not compare with those obtained by proper mechanical treatment.

The President said that, owing to the lateness of the hour, he would not prolong the discussion further than to state that he believed that treatment by mechanical appliances could be aided and shortened by general therapeutical means, of which he would speak in some future meeting of the Section on Orthopædic Surgery.

Dr. Shaffer said that he had been unable to differentiate between tubercular and syphilitic cases, except that in some instances the patients recovered under the influence of what was known as anti-syphilitic treatment, while in others they did not. In private practice he would use internal medication as an adjunct. The cases which they had observed as the basis of the paper were dispensary cases, and showed that, with a proper workshop and a competent corps of assistants, the work

of four or five hospitals could be done successfully in an institution of that character.

He did not intend to consider

MECHANICAL TREATMENT *vs.* EXSECTION,

but merely to show that a large number of cases of hip-joint disease could be treated at home. He believed, however, that under proper internal medication, with mechanical treatment and the patients under the best hygienic influences, a larger percentage of recoveries with better results could be obtained—provided that amyloid degeneration of any of the organs was not present—than would be secured by excision.

Eight years were not consumed in controlling the discharge and sinuses, but in getting the limb into the proper position for the patient's discharge from treatment—the position which would render the limb most serviceable. Most of the long cases were

DRY CARIES,

in which the worst position of the limb and the greatest deformities were most likely to be encountered. He was not opposed to excision, but believed that the cases were rare in which it should be performed.

THE PRESIDENT announced that at the next meeting the subject of *Empyema* and its treatment would be discussed in a series of short papers; after which the Academy adjourned.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, held in Washington, D. C., May 11, 12, 13, *and* 14, 1887.

WEDNESDAY, MAY 11TH—FIRST DAY—MORNING SESSION.

THE PRESIDENT, DR. HUNTER MCGUIRE, of Richmond, Va., delivered the opening address, on

THE NEED AND VALUE OF CO-OPERATIVE WORK IN SURGERY.

He said that he would occupy the time briefly, not with a discussion of some surgical subject, for the programme showed how rich the supply of material was in that direction, but with some remarks concerning the need and value of co-operative work in our profession, and afterward in suggesting some changes in the management of the meetings of this Association. Nearly every advance in whatever is accomplished by human enterprise is secured by co-operative effort. Every department of life is full of illustrations of the power of association in the accomplishment of great purposes, while the illustrations are almost as numerous of the failure of individuals to attain those ends, because they work unaided and alone. Advance in surgery can be more surely made by associations such as ours than by any individual efforts of man. The day has passed when the dictum of one man, no matter how exalted he may be, is received without question. The difficulties which beset us are numerous. Disease presents problems difficult of solution. We cannot apply to the human machine the fixed rules by which inanimate bodies are governed. The result of the work of the surgeon in private houses and in public hospitals must be different. Besides this, it is necessary to get rid of the rubbish with which we are too often flooded by ignorant but ambitious contributors. This is an easy task, but it is more difficult to know when to reject the material presented by skilful but unscrupulous workers who, to gratify their own personal vanity, make false returns of their labors.

I have mentioned only a few of the difficulties by which we are surrounded. Their influence over the true man, the true surgeon, should be to make him more patient, inspire him with more zeal, and teach him more plainly the value of co-operative industry. For the developments yet awaiting us we must be indebted to the contributions which every patient and conscientious laborer may bring to the common stock of ascertained knowledge, and we shall accomplish this best by the cultivation of a broad and generous appreciation of each other's work, from which every particle of envy at the success of others has been eliminated; by the hearty commendation which we give to all who have enlarged the boundaries of surgical science or who have improved its art.

In concluding his address the President made the following suggestions:

1. The formation of a business committee to prepare the work of the Association. The committee should select two general subjects in surgery to be discussed at the morning sessions of the first and second days.

2. The address of the President should be limited to half an hour, readers of papers to the same length of time, and those who take part in the discussions to fifteen minutes.

3. I venture to suggest the abrogation of Article 9 of the Constitution. This will allow us to admit to fellowship some men in this country who are really needed in the Association. While I believe in the rigid observance of the Code of Ethics of the American Medical Association and the absolute necessity of its enforcement in that body, there is no need for it in our Association. The only code that we should have is scientific work.

4. That the report of the committee with reference to the American Congress of Physicians and Surgeons be adopted.

5. That the constitution be so amended that propositions for membership shall lie over for one year. The qualifications for fellowship should be age, experience in surgical work, scientific attainments, with general culture.

A committee of three was appointed to take into consideration the suggestions offered by the President. The committee consists of Drs. S. W. Gross, C. H. Martin, D. W. Yandell, Moses Gunn, and C. Johnston.

The Association then went into executive session.

AFTERNOON SESSION.

DR. F. S. DENNIS, of New York, read a paper on

THE EXPLORATION OF THE BLADDER BY THE SUPRA-PUBIC METHOD.

A brief historical account of the operation was given. The first reported operation was that of Franco, in 1561. From that period to 1879 the operations were not numerous, but from 1879 to the present time the operation has been done with such success as to attract attention throughout the world. The time is not far distant when practically the only two operations will be supra-pubic lithotomy and litholapaxy. Supra-pubic lithotomy is simple in technique, safe in execution, free from injury to the reproductive organs, radical in results, curative in application, and brilliant in statistics. The many serious accidents attending the lateral operation are avoided. For a few days before operation a milk-diet should be employed. The day previous to operation the bowels should be moved with castor-oil. The morning of the operation an enema should be used, so as to empty the rectum for the introduction of the rubber bag. The parts should be washed with antiseptic solution. After the patient has been etherized the surgeon should introduce a rubber bag into the rectum so as to be above the internal sphincter. Into this twelve ounces of warm water is to be introduced. This quantity will have to be increased or diminished according to circumstances. The danger of rupture of the rectum in elderly people and young boys should be borne in mind. The urine should be withdrawn and six ounces, more or less, of an antiseptic solution introduced into the bladder. The catheter may be left in the bladder and stopped with cork, and this will serve as a guide to cut upon. The distention of the rectum and bladder increases the distance from the pubes to the anterior cul-de-sac of the

peritoneum to three inches. The incision should be made in the median line, and should extend for three or four inches above the pubes. When the transversalis fascia is reached the use of retractors, on the principle of the eye-speculum, facilitates the operation. Having divided the fascia, the end of the catheter can be felt and cut upon as a guide. The bladder may then be seized with two tenacula and opened. Where free exploration is desired sutures are introduced on each side of the incision. The stone is removed either with the fingers or forceps. The bladder may then be washed out. A catheter should be introduced through the urethra, but not left longer than twenty-four hours, on account of the danger of exciting traumatic urethritis. In the majority of cases the wound of the bladder should be left open. In cases of calculi the condition of the tissues is such that primary union is unlikely. In certain other conditions, such as rupture, the wound may be closed, for here the condition of tissues is different. The abdominal opening is to be closed and a tube introduced.

This operation is indicated (1) for hard, large calculi, and in persons suffering with paraplegia and deformities rendering lateral lithotomy difficult; (2) for removal of certain foreign bodies, such as hair-pins, etc., and for the treatment of chronic cystitis; (3) in cases of tight stricture, fibroma of prostate, tumors of the bladder, and for rupture. In its extraordinary simplicity, its reduced mortality, its freedom from danger, and safety for the general practitioner, it compares well with litholapaxy.

The speaker had collected one hundred and twenty-four cases of supra-pubic operation for stone done since 1879. Previous to this date the rate of mortality was thirty per cent. Since then the mortality has been reduced, there being eighteen deaths, a mortality of fourteen per cent. Seven of these deaths may be justly excluded, giving a mortality of nine per cent. According to Sir Henry Thompson's statistics, the death-rate from the lateral operation is twelve per cent. According to the same authority, the mortality of lithotrity is six per cent. In considering the mortality of this operation, two facts are to be considered. The mortality may be improved by more rigid antiseptic precautions. The second fact is that the operation has been limited to the largest stones. When the smaller stones are included the death-rate will be reduced. Specimens showing the position of the bladder under various conditions were then shown.

Dr. John H. Packard, of Philadelphia, read a paper on

SUPRA-PUBIC CYSTOTOMY FOR OTHER PURPOSES THAN THE REMOVAL OF CALCULI.

In 1883 the speaker removed, by supra-pubic cystotomy, a piece of shawl-pin five inches in length, which had been passed through the urethra. Since then he has done this operation a number of times. In cases of retention of urine from stricture, where a fair attempt to pass an instrument fails, he draws the urine by aspiration. In a short time an instrument can usually be passed. He did not recall a case in which it was necessary to repeat aspiration. The following cases were cited:

July 7, 1855. — Mr. G——, aged eighty-five, had retention due to large prostate. The bladder was greatly distended. The urine was drawn off with a long catheter; but he desired more permanent relief. Supra-pubic cystotomy was performed, and a glass ovariotomy tube, bent like a tracheotomy tube, was introduced. The patient improved decidedly, but suddenly died, July 9th, from heart, failure, the result of sudden exertion.

J. C——, aged forty-three, came under observation, January 21, 1885, at the Pennsylvania Hospital, with a history of retention, the result of old stricture. The bladder was greatly distended, and no instrument could be passed. There were frequent chills and profuse sweats. The next day Dr. Thomas G. Morton made a perineal incision, opening an abscess; the catheter then passed into the bladder. The following day the bladder was again distended. Supra-pubic incision was then done, a catheter passed through the abdominal opening, and the neck of the bladder escaped through the perineal wound. On February 7th a large mass of slough came from the abdominal wound. The patient then rapidly improved, and was discharged cured, April 21st.

H. F——, aged forty-three, had retention for four days. The penis, scrotum, and skin of abdomen were swollen, tense, and rigid. Free incisions were made. The bladder was opened and a tube introduced. On June 4th an instrument was passed by urethra. On July 13th the patient was discharged, and has continued well.

Mr. S——, aged sixty-three, admitted with enlarged prostate and frequent attacks of retention. August 13, 1886, supra-pubic incision was performed and the bladder opened. Although the condition was improved the patient died of exhaustion, August 29th.

The next two cases occurred at the Pennsylvania Hospital within the past few weeks. W. E——, aged seventy, was admitted, April 24, 1887, with retention due to enlarged prostate. Supra-pubic cystotomy was performed and a large quantity of putrescent urine removed. A rubber tube was passed into the bladder. The urine contained albumen to the amount of one-half its bulk. Granular casts were also found. A typhoid condition developed, and the patient died on the fourteenth day after admission.

R. W——, aged forty, was admitted the same day; he had double inguinal hernia and double hydrocele. He had passed no urine for fourteen hours. Catheterization was attempted without success. Supra-pubic incision was then performed, and a rubber tube introduced. He has done well since then, and is beginning to pass some water by the urethra.

Method of procedure.—The fullest antiseptic precautions should be observed in these cases. In most of the cases on which the author had operated the question whether or not the bladder should be distended had not presented itself, as the bladder was already over-distended. The bladder should never be more than moderately distended, not more than six or eight ounces of a boric-acid solution being employed. To retain the water in the bladder a convenient method is to bend the urethra on itself and hold it in this position. There seems to be more advantage and less risk from distention of the rectum. Many writers recommend that the bladder be steadied by an assistant, but this was regarded as needless and objectionable.

The incision through the skin should be free enough to give ready access to the deeper parts. When the bladder is reached it is desirable to secure it in some manner before puncturing. For this purpose a small double hook may be used; a small tenaculum may answer. When a large opening is to be made a double ligature is, perhaps, the best device. In cases of retention the curved trocar and cannula may now be at once used; the cannula should afterward be substituted by the tube. The speaker's custom is to make the opening in the bladder just large enough for the tube. The proper point for making the opening seems to be about at the middle of the exposed portion of the wall of the bladder, which would be about one inch or one and one-half inch above the pubes.

The drainage-tube should go well into the bladder and have lateral openings only near its extremity. The external end may be closed with a cork or clip, or by bending it. In old men with atonied bladders he had sometimes used glass tubes. If a large opening has been made in the bladder it may be closed around the tube with a few catgut sutures. The tendency of the wound is to close quickly, except where the tissues, as well as the general system, are in bad condition. The edges of the wound in the skin can be apposed with sutures of catgut or silkworm gut.

In concluding, the speaker asked: If the supra-pubic section had been first tried and generally adopted, is it likely that the perineal operation would have been afterward performed on account of its greater ease, simplicity, and efficiency?

Dr. A. Vander Veer, of Albany, N. Y., read a paper entitled

TO WHAT EXTENT CAN WE CLASSIFY VESICAL CALCULI FOR OPERATION? WITH A REPORT OF CASES AND REMARKS ON THE DIFFERENT METHODS EMPLOYED.

The speaker gave the detailed histories of forty-one cases which he had operated on. The various methods employed were lithotomy, rapid dilatation of the urethra, and Bigelow's operation (litholapaxy).

There were seven cases of perineal lithotomies, with two deaths and five recoveries, the former being very old men with large stones. Of attempted litholapaxies and an immediate perineal lithotomy there were two cases, both resulting in death, one occurring in the speaker's practice, the other in the practice of a friend. Both were severe cases of large stone, the patients presenting a history of much suffering through many years. Of dilatation of the urethra in the female, and washing out of fragments or removal of stone entire, there were six cases, all recovering, with no complication whatever. Of urethral calculi in the male there were four cases, all recovering. Of simple lithotrity in the male there was one case, followed by recovery.

Of attempted litholapaxies, but which were not completed, there were four cases, three ending in death and one, the stone hiding in a sac, later underwent perineal lithotomy and recovered. One was probably complicated with some form of tumor of the bladder, and a history of chronic disease of the kidneys. One was a case of chronic alcoholism, one was complicated with sacculated bladder, and the last two were cases of surgical kidney of the very gravest kind.

Of the litholapaxies in the male there were eighteen patients, having twenty-two operations, four requiring a second operation. Of the number, sixteen recovered and two died; of the latter, one after the first and one after the second operation.

With reference to supra-pubic lithotomy, the author said that, with the excellent results we are ever likely to obtain from rapid lithotrity, the operation must necessarily deal with severe cases of large, and in some instances sacculated, stone. He did not believe that we should ever expect from it as great a per cent. of recoveries—it is hardly possible. A table of reported cases of supra-pubic operations was given, showing in 142 adult cases a mortality of twenty-two per cent.; in children under fifteen years of age 113 cases gave a mortality of 10.5 per cent.

The operation of litholapaxy is certainly indicated where the stone is small or of moderate size, and, contrary to the teachings of a few years since, can be done in very young male children with proper instruments. In male adults, if there is severe chronic cystitis, no matter what is the size of the stone, the supra-pubic or some form of perineal lithotomy seems best. The cystitis can then be successfully treated, and there is less danger of a reformation. The speaker thought that it would be found by future statistics that cystitis has much to do with the necessity for a second or third operation. He thought that contracted bladder in the male, with adhesions, had not received the attention which it demanded. This must, in some instances, embarrass supra-pubic lithotomy. On anatomical grounds the supra-pubic operation will be much simpler in the youth, as the bladder is much higher in the pelvis at this time of life. In girls rapid dilatation or supra-pubic lithotomy will undoubtedly reach all cases. In adult women vaginal lithotomy may be added.

The discussion of these papers was postponed until Thursday morning. Adjourned.

THURSDAY—MAY 12TH—SECOND DAY—MORNING SESSION.

THE COMMITTEE OF CONFERENCE WITH REFERENCE TO THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

reported that it had attended the meeting of conference held in Washington, September 24, 1886. At this meeting the following resolutions were adopted:

Resolved: 1. That it is desirable that the following special societies, The American Surgical Association, The American Ophthalmological Association, The American Otological Association, The American Neurological Association, The American Laryngological Association, The American Gynecological Association, The American Dermatological Association, The American Climatological Association, with the Association of American Physicians, shall arrange for a conjoint meeting in the city of Washington, September, 1888, and subsequently at intervals of three years at the same time and place.

2. That this arrangement shall not interfere in any way with the autonomy of each special society; and that each society shall retain the right to withdraw at any time from this conjoint scheme.

3. That the special feature of the meeting shall be the conjoint assemblage of the special societies on two evenings during the session, on one of which there shall be an address delivered by the President of the conjoint meeting, and on the other there shall be communications by a referee, and a referee on some subject of general professional interest.

4. That each special society approving this report is invited to appoint one representative (with an alternate), and that the representatives so appointed shall constitute an executive committee to serve for one year, with power to select such officers for the first conjoint meeting as may be deemed necessary; to propose a programme for said meeting; to make all other arrangements, and to prepare and submit a plan of organization for future meetings.

5. That all expenses connected with the conjoint sessions shall be apportioned equally by the Executive Committee among the special societies participating.

Owing to the views entertained by the Committees of the Ophthalmological and Dermatological Associations with regard to the interval of times of meeting, they abstained from voting upon the first resolution.

The report was adopted, and Dr. C. H. Masten, of Mobile (with Dr. J. Ford Thompson, of Washington, as alternate), was appointed as the representative of the Association.

The following was announced as the Nominating Committee: Drs. J. Collins Warren, J. Brinton, T. F. Poewitt, N. P. Dandridge, and D. W. Yandell.

The Treasurer, Dr. P. S. Conner, reported a balance of $738.46 in the treasury.

The discussion of papers read on Wednesday was then taken up.

Dr. W. T. Briggs, of Nashville, held that the surgeon should have all operations at his command, and should select the one adapted to the particular case. In certain cases, such as large stones, or deformities of pelvis and lower extremities, supra-pubic lithotomy is undoubtedly the best operation. The operation which he regarded as the best is one through the median line. There is no reason why fragmentization of a large stone should not be combined with the medio-lateral operation. The operation is easier than the lateral operation. Incision in the manner mentioned, with the removal of all stones at once, he thought would have a less mortality than litholapaxy.

Taking all kinds of cases, at all ages, his first seventy-four cases were operated on by this method without a death. Then he had two deaths; in one a pelvic abscess complicated the case, and in the other there was scrofulosis. Forty-six cases were then operated on, with one death. This case died three months after operation, of

general tuberculosis, with wound ununited. It is probable that in properly prepared patients, without organic disease, the mortality will be nothing.

Dr. D. Hayes Agnew, of Philadelphia, said we cannot commit ourselves positively to any one operation. The median operation is undoubtedly the safest operation through the perineum. The only damage likely to be done is in extraction; but this can be avoided by nicking the neck of the bladder, which admits distention to almost any extent. Where the stone is large, and yet is one which should come through the perineum, an incision may be made on each side. Drainage is more readily effected by the perineal operation.

Dr. J. R. Weist, of Richmond, Ind., had performed the medio-bilateral operation in eight cases, all of which recovered. With one exception all the patients have been old. From the accounts of the supra-pubic operation given yesterday, he inferred that the operation is more difficult of performance than the one described by Dr. Briggs.

Dr. H. H. Mudd, of St. Louis, stated that his first operations were performed by the perineal method, with good results. He then began the use of litholapaxy, which, in the majority of cases, takes the place of the perineal operation. The supra-pubic operation is of service for the removal of certain large stones, and for exploratory purposes. In considering this operation it must be borne in mind that the existence of contracted bladder with adhesions will render the supra-pubic operation difficult or impossible. Instances in which this condition was present were related.

Dr. J. Collins Warren, of Boston, stated that during the past year he had seen two cases of the supra-pubic operation, both in the practice of others. One was for stone and the other for tumor. There seemed to be no difficulty in the operation. Both cases recovered without a bad symptom.

Dr. Theodore Varrick, of Jersey City, had removed through the perineum a stone weighing seven ounces and two scruples. There was no perceptible laceration, and the boy recovered completely.

Dr. David Y. Yandell, of Louisville, had performed ninety-two operations by the perineum, eight by lithotrity and six by litholapaxy. It did not seem to him that the supra-pubic operation was an easier or better one than those which he had mentioned. There were seven deaths from the lithotomies. In none of the cases was there any return of the stone. In the eight lithotrities there was a return of the stone in two cases. In the six Bigelow operations there was a return in two cases.

Dr. John B. Roberts, of Philadelphia, considered the high operation certain to be a very important one. If we wish to make a free exploration of the bladder, the high operation is better than the one through the perineum. In cases of stone operated on by a surgeon without special experience in this direction, the supra-pubic operation is the safer. With reference to Dr. Packard's suggestion to treat retention of urine from stricture by supra-pubic cystotomy, he considered this too serious a step to take in the first place. His view was that persistent efforts should be made to introduce a filiform bougie which will drain off the urine. Simple aspiration above the pubes will give a chance for the passage of an instrument through the urethra in two or three days.

Dr. J. E. Michael, of Baltimore, said that supra-pubic aspiration seems to be all that is necessary for retention due to stricture or prostatic disease, and, under proper precautions, is safe. In prostatic cases the use of a soft catheter will accomplish all that can be done, unless some radical operation is attempted. As to the advisability of the supra-pubic operation for exploration, for some cases of prostatic enlargement, and for exceptional cases of foreign bodies, there can be no question. It was an operation which promised more in selected cases, than any procedure with which he was acquainted, and taking all considerations into account, was not attended with special danger.

Dr. J. Collins Warren, of Boston, read a paper entitled

A STUDY OF THE PROCESS OF REPAIR AFTER RESECTION OF THE INTESTINES AND SOME OF THE COMPLICATIONS WHICH OCCUR.

The author referred to the anatomy of the wall of the intestine, calling particular attention to the thin submucous, fibrous coat, which was the strongest of the various coats of the intestine. In introducing the sutures in cases of wound of the bowel it is desirable that a few fibres of this fibrous coat be included, but care must be taken not to perforate the mucous membrane. A number of experiments made upon dogs was then described. The operation consisted in removing a portion of the intestine and a V-shaped portion of the mesentery, and then bringing the parts together. The Lembert suture was the one used. The dogs were killed at varying times after operation, from three to eight days. In these cases the intestines were found matted together around the seat of operation, but a current of water flowed freely through the gut. In one case the abdomen was opened a few days after operation, and this matting together of the various coils of intestine found. The intestine was replaced and the wound again closed. Six months later most of the adhesions were found to have disappeared.

Dr. Charles B. Nancrede, of Philadelphia, read a paper on

SHOULD LAPAROTOMY BE DONE FOR PENETRATING GUNSHOT WOUNDS OF THE ABDOMEN INVOLVING THE VISCERA?

Reference was made to the experiments of Wegner and Grawitz, showing that the healthy peritoneum can dispose of air, serum, bile, and healthy urine. When, however, air and putrescible fluids in greater amount than could be disposed of in a short time were introduced, decomposition occurred and septicæmia resulted. A notable exception was that living, defibrinated blood never decomposed under these circumstances. This seems to prove the truth of the suggestion of the author that the presence of fibrin-ferment, and probably its absorption, is one of the dangers of peritoneal traumatism. The ordinary micro-organisms produce no evil effects, provided the quantity of putrescible matter does not exceed that which may be disposed of in a short time. In small quantities the pathogenic micro-organisms produce no harm. Suppurative peritonitis is produced by these micro-organisms when stagnant fluids are present capable of nourishing the bacteria, when the surface of the peritoneum has been destroyed by caustic fluids, and when there is a wound of the peritoneum.

The practical application of these experiments teaches that all blood and serum should be removed and free drainage provided; every wounded surface must be coaptated; if a tube is used, the opening must be carefully guarded; the depression of the circulation present during shock must be removed, and the vascularity of the peritoneum must be kept as near the normal as possible.

When visceral wounds do undoubtedly exist the tendency of these cases is invariably toward death. Hemorrhage in itself is rarely fatal, but a very small collection of blood may be followed by fatal consequences, either through the induction of sapræmia, or by furnishing pabulum for the development of organisms productive of suppurative peritonitis. In nearly every case death is due to septic peritonitis caused by extravasated matters. Of those attacked with peritonitis ninety per cent. die within twenty-four hours. When recovery ensues the effused matter is absorbed, and a limited adhesive peritonitis glues the injured organ to the abdominal walls or to a neighboring viscus. This process is successful in about eight per cent. of the cases.

Shock and the risk of rendering a peritonitis septic and diffused, which might have remained local and simple, are the dangers of laparotomy. But as we have the

power of rendering the inflammation resulting from the manipulations innocuous, shock is practically the only result to be dreaded.

If these facts and the deductions from them be true, all ball wounds of the abdomen involving the stomach, intestines, bile, or urinary bladder should be treated by suture or by resection and suture; injured omentum should always be excised, and the serous surfaces carefully sutured. Wounds of the liver and pancreas are to be treated in the manner to be described. A wounded spleen or kidney is to be removed, provided certain contraindications do not exist. Even penetrating wounds of the abdomen without involvement of the viscera are better treated by exploratory section than by the expectant method. In many instances unsuspected injuries of the blood-vessels and viscera will be found and appropriately treated. The track of the ball should be enlarged, under aseptic precautions, until it has been determined whether or not the peritoneum has been opened. Then median section should be performed to ascertain the existence of and repair any damage that may have been done. The above remarks can only apply to wounds of the anterior and lateral walls of the abdomen. When the posterior wall is involved, it is unadvisable to ascertain the fact of peritoneal penetration by direct exploration. In these cases a correct opinion is almost always difficult and often impossible without laparotomy.

Profound shock, if not due to hemorrhage, is a contraindication to operation. The surroundings should not contraindicate operation in a proper case provided the operator be expert in abdominal surgery. Most cases will do better if left to nature than they will if operated on by a bungling surgeon. If well-advanced peritonitis exists, laparotomy is contraindicated. Where there is no visceral complication, operation under these circumstances may sometimes be justifiable. Laparotomy, if done at all, should be done at the earliest possible moment that the condition will admit of it. Shock is the only thing that should delay the operation, and this should not do so if the condition is produced by hemorrhage.

In operating strict antiseptic precautions should be carried out. The incision should always be median, extending from a short distance above the umbilicus to two inches above the pubes. Unless there be free hemorrhage the small intestines should be carefully gone over, keeping them constantly enveloped in towels wrung out of hot water. Afterward the stomach, spleen, kidneys, bladder, etc., must be carefully examined. The source of a severe hemorrhage must at once be sought after. Wounds of the bowel should be secured with the Lembert suture and dusted with a little iodoform. Wounds of the liver, if occupying its free border, should be coaptated, if possible, with dry aseptic catgut, which will soon swell and fill the track made by the needle. If this cannot be done, the hemorrhage possibly may be arrested by the thermo-cautery, or if the bleeding is free, the wound should be plugged with an iodoform gauze tampon. If at the close of the operation the bleeding is almost completely checked, the cautery may be used as a further protection, and the tampon removed. If, however, the bleeding is still free, the tampon should be replaced and allowed to remain permanently. Wounds of the pancreas, spleen, and kidneys are to be treated in a similar manner. If these measures fail the spleen or kidney is to be removed. Wounds of the bladder had better be united with dry catgut. Contused portions of the bowel should be excised. Wounded or contused omentum or mesentery should also be removed. In removing a portion of the bowel the cuts should correspond to the distribution of a large mesenteric branch. Should the pulse fail during the operation, flushing the abdominal cavity with hot water is often of service. The peritoneal toilet is most quickly and effectively made by irrigation with warm sterilized water and subsequent removal with sponges. Wounds of the peritoneum should be united. In closing the abdominal cavity, the peritoneum should be sutured with fine silk or catgut. The muscular aponeurotic and cutaneous structures should then be united with strong silk. The wound should be dusted with iodoform, and the dressing completed by the application of a pad of absorbent cotton and a flannel bandage.

Alimentation should be carried on by the rectum for forty-eight hours when possible. Where peritonitis comes on after the operation, the treatment will depend upon whether it has developed rapidly or gradually. In the former case there is often evidence of shock from vasomotor paresis, and in these cases small doses of morphia with atropia will be of service, while large doses of opium may prove fatal. This should be continued until pain is relieved and the patient falls into a quiet sleep, from which he is readily aroused. In the latter stages of peritonitis one or more hypodermics of atropia will at times save otherwise hopeless cases. For the control of the vascular processes involved in peritonitis we have two powerful measures in the ice-coil to the abdomen and in the use of leeches if applied early and the patient has not lost much blood. If the temperature continues to rise, despite treatment, it is probable that ptomaines are being absorbed, producing sapræmia. In such cases, irrigation with safe antiseptic fluids is indicated.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 8 to May 14, 1887.

ALEXANDER, C. T., Lieutenant-Colonel and Surgeon. Granted leave of absence for four months, with permission to go beyond sea, to take effect May 23, 1887. S. O. 105, A. G. O., May 7, 1887.

HARVEY, P. F., Captain and Assistant Surgeon. Granted leave of absence for four months, with permission to go beyond sea, to take effect June 10, 1887. S. O. 105, A. G. O., May 7, 1887.

BIART, VICTOR, Captain and Assistant Surgeon. Ordered for examination by Army Retiring Board at Fort Leavenworth, Kan. S. O. 107, A. G. O., May 10, 1887.

ELBREY, F. W., Captain and Assistant Surgeon. Ordered for examination by Army Retiring Board at Washington, D. C. S. O. 109, A. G. O., May 12, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 14, 1887.

GRAVATT, C. U., Surgeon. Detached from U. S. S. Michigan.

LUMSDEN, G. P., Passed Assistant Surgeon. Ordered to the U. S. S. Michigan.

ASHBRIDGE, RICHARD, Passed Assistant Surgeon. Detached from the Naval Academy and ordered to the Practice Ship Constellation.

STREETS, THOMAS H., Passed Assistant Surgeon Promoted to Surgeon.

THIRST IN YOUNG INFANTS.—It is a mistake to suppose that because milk is a liquid food it is at the same time a drink which is capable of satisfying the thirst of infants. Although milk appeases hunger, it makes thirst more intense after it has remained some time in the stomach and digestion of it has begun. It is thirst which causes healthy, breast-nourished infants to cry for long periods of time in many instances. There are many cases of indigestion due to weakness or insufficiency of the child's gastric juice which would be greatly benefited or even cured if the child were allowed an occasional drink of water.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 14, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	2
Scarlet fever	72	9
Cerebro-spinal meningitis	2	2
Measles	91	8
Diphtheria	120	46
Small-pox	11	5
Yellow fever	0	0

To Arrest Nasal Hemorrhage.—In persistent hemorrhage from the nasal cavity, plugging the posterior nares should not be done until an attempt has been made to check the hemorrhage by firmly grasping the nose with the finger and thumb, so as completely to prevent any air from passing through the cavity in the act of breathing. This simple means, if persistently tried, will, in many cases, arrest the bleeding. The hemorrhage persists because the clot which forms at the rupture in the blood-vessel is displaced by the air being drawn forcibly through the cavity in the attempt of the patient to clear the nostrils. If this air is prevented from passing through the cavity, the clot consolidates in position and the hemorrhage is checked.—*Edinburgh Medical Journal.*

Sugar in the Blood.—A series of researches has been completed by Professor Seegen, of Vienna, which would appear to show that the sugar formed by the liver is derived from albumen and fat. Seegen also believes that the blood passing from the liver contains an infinitely greater quantity of sugar than that entering the organ. That the newly formed sugar in the liver is wholly independent of saccharine food, as well as of the carbohydrates introduced with the food. That even the hepatic glycogen is unconcerned in the production of sugar in the liver. The fact that sugar is formed from fat is a new one, and is not in accord with previously entertained chemical and physiological ideas. It appeared to the author, therefore, of much interest to experimentally demonstrate the conversion of fat into sugar. This was accomplished by bringing together fatty bodies and blood with finely divided liver-substance. The settlement of this question, that sugar is formed from fat by the liver, seems to point to that organ as the great laboratory in which the food is changed for the purpose of life, for the performance of work, and the production of heat. It has a great practical significance, inasmuch as it teaches us the full worth of fat as material for food. —*Weekly Medical Review.*

For a crying, irritable, peevish infant, Professor Bartholow speaks very highly of the following:

℞. Sodii bromidi..... gr. v
Mist. asafœtidæ.....f ʒ j M.

Sig.—*Pro re natâ*

If there be no flatulence, simply give the bromide in camphor water.

Fasting Exhibitions.—They do these things differently in Germany. The enterprising individual named Cetti, whose exhibitions in Italy and in Paris last year will be remembered, proposed recently to make exhibition of his fasting powers (for money) in Berlin, but the authorities very properly prohibited the stupid exhibition. The *Medical Press* supposes an Act of Parliament would be required in our favored free country (*i. e.*, England) before any city authorities would dare to take such high-handed action in the case of an exhibition, however senseless, so long as there was no actual danger to life.

Chloroform and Ether.—Dr. J. P. Wilson, of Poughkeepsie, writes that, after a considerable experience with anæsthetics, he has come to the conclusion that the best way is to use both chloroform and ether. He begins with ether, and after the choking sensation has passed away, combines the two until complete relaxation has been produced, when chloroform alone is used. In childbirth and for children he uses chloroform alone.

The Prognosis in Acetonæmia.—Dr. J. C. Neal, of Archer, Fla., referring to the article by Dr. Cheesman on "Acetonæmia," writes: "For some years I have felt obliged to pronounce a fatal prognosis in the fevers incident to Florida, whenever the fruity, vinegar-like odor appeared in the breath, especially if the urine had a specific gravity of over 1.024. This odor is noticeable a day or two before death, and the wine-red reaction of the urine with ferric chloride occurs generally within a few hours of the fatal coma. I look upon these tests as exceedingly valuable, especially the fruity odor, and when it has occurred in cases of malarial hæmaturia, marasmus, cholera infantum, and continued fevers, I have never witnessed a recovery."

Professor Ball's Treatment of the Morphine Habit consists, first, in placing the patient under strict watch in a maison de santé; second, in taking away the morphine more or less completely; third, in giving hypodermatic injections of sparteine to relieve the cardiac depression. Sometimes a little morphine is added, and sometimes nitroglycerine is given also.

A Six-fingered Family.—A communication having reference to twenty-seven individuals and five generations is summarized as follows in the *Rev. Internat. des Sci. Méd.* First generation: Man, born in the year 1752, had six toes on one foot. Second generation: A son with six toes on one foot; a daughter, normal. Third generation: This daughter had five children, among whom were a son and daughter each having six fingers on each hand. Fourth generation: The daughter last mentioned had eight children, including one son having six toes on one foot, another son and two daughters each having six fingers on each hand, and one daughter having both six fingers on each hand and six toes on each foot. Fifth generation: The daughter last mentioned (the *Revue* makes a mistake here) had three children, including a son doubly deformed like his mother, and a son with six fingers on each hand, the feet being normal. Moreover, one of the two daughters of the fourth generation (with only the hands affected) had eight children, several of whom were normally developed, but the rest were deformed as follows: One daughter had an osseous thickening at the digital extremity and on the outer border of the fifth metacarpal; one son had six fingers on each hand and six toes on each foot; and another son had six fingers on each hand. Thus, in the first generation, one person was affected, and in the second also one; in the third, there were two cases of deformity; in the fourth, five; and in the fifth, in all five; that is, fourteen deformed persons altogether during five generations of this interesting family.—*British Medical Journal.*

Wiring the Patella—Pyæmia—Death.—A patient was brought to St. Mary's Hospital, Quincy, Ill., in the service of Dr. William A. Byrd. He had an old fracture of the patella, the two pieces of bone being separated for five inches when the leg was flexed. The limb being perfectly useless as it was, he was very anxious for the patella to be repaired. The bones were cut down upon, and each piece transfixed by two wires. By tightening the wires the parts were brought nearly together. Tenotomy of the quadriceps femoris was required before they could be brought into close apposition. The wires were twisted; through and through drainage established at the lower part of the knee's joint. He did well for a while, but pyæmia ensued, of which he died.

A RARE FORM OF SEPTICÆMIA FOLLOWING OPERATION FOR URETHRAL STRICTURE; SEPTICEMIE GAZEUSE FOUDROYANTE.[1]

BY R. W. TAYLOR, M.D.,

SURGEON TO CHARITY HOSPITAL, NEW YORK.

THREE reasons prompt me to report the following case. First, because it illustrates a form of septicæmia not generally known or systematically described in the English language; second, because its history presents a typical clinical description of this rare and deadly affection; and third, because it is unique, I think, in literature, as an illustration of the complication of an urethral operation by this form of septic infection.

In the spring of the year 1878 I was asked by an esteemed colleague, now deceased, to assist him in an operation for urethral stricture, and, if the precarious state of his health rendered it necessary, to take more or less complete charge of the subsequent treatment. The patient was a man, aged twenty-eight, of temperate habits and athletic build. His stricture had followed several attacks of gonorrhœa, from which he had suffered during the previous nine years. Otherwise he had enjoyed perfect health. His urine was examined several times prior to and just before the operation, and found to be normal. The stricture was at the bulbo-membranous junction, and admitted a No. 4 bougie, French scale. Under ether this stricture was incised by means of Maisonneuve's instrument, and a steel sound No. 32, French scale, was passed, without any hitch, into the bladder. The operation was performed on Sunday at 4 P.M. I need scarcely add that every attention to cleanliness was observed, and that the operation was uncomplicated by any drawback, such as we sometimes experience, requiring withdrawal and reinsertion of the cutting instrument, or repetition of the confirmatory introduction of the sound. In fact, the utmost care and gentleness were observed, and we both thought that there had been no unnecessary wounding of the tissues. Quinine was given when the patient came out of the ether. All seemingly went well, until Monday morning. The urine was passed freely four hours after the operation, and the patient slept tolerably well all night. At noon on Monday he complained of a dull, uneasy sensation in the perineum, of languor and want of appetite, and informed us that he had not urinated since the previous evening. His temperature was 101° F.; tongue rather dry and coated, and skin dry. A hydragogue cathartic was given at once, which operated freely on the bowels. A small quantity of urine was voided. In the evening the general condition was similar to that of the morning, except that the temperature had reached 104° F. Infusion of digitalis was given to stimulate the kidneys, and ten minims of Majendie's solution were injected into the arm to cause sleep and relieve the restlessness and anxiety of the patient. A specimen of urine, of which a small quantity had been passed during the evening, was examined by me and found to be bloody in appearance, acid in reaction, of a specific gravity of 1.028, highly albuminous, and to contain hyaline and granular casts in abundance, and blood- and pus-corpuscles. His sleep was broken and troubled during Monday night, and on the following morning we found him utterly prostrated by weakness, very nervous, anxious, restless, with headache, nausea, and great thirst. Temperature was 102° F., tongue parched, skin dry, urine scanty, and bowels inactive He had taken Vichy water and milk and infusion of digitalis. The patient complained of great pain in the perineum. We found the tissues in the course of the urethra from the base of the scrotum to the verge of the anus swollen and boggy. A flaxseed poultice was ordered to be applied continuously. The situation in the evening was similar, but rather more pronounced. The temperature was 105° F. The bogginess, which had early in the day been limited to the perineum, had at 9 P.M., Tuesday, extended fully six inches to the left and was the seat of preternatural heat. Poultices were continued. The existence of the extravasation of urine was at first suspected, but the subsequent course of the case showed that that diagnosis was not warranted.

To quiet the extreme anxiety and restlessness fifteen drops of Majendie's solution were injected into the hypogastrium, with the hope of also allaying the local pain. At 2 A.M. on Wednesday I was summoned in great haste, my colleague being too ill to leave his bed. I found the patient in great mental and physical agony; so restless was he that he could hardly remain in one spot, and so utterly weak and prostrated that he could scarcely move. His sufferings had been much increased within the past six hours by severe dyspnœa. The temperature had fallen to 102° F., the pulse was 110 and filiform, and the action of the heart tumultuous. His facies wore a pinched and agonized look, with a deadly earthy pallor, and sunken eyes surrounded by dark circles. The whole of the left buttock, beginning at the urethral region, presented a very peculiar appearance. The integument, as far as the crest of the ilium, was distended, tense, and hot. Pressure upon it revealed œdema and emphysema. The peculiar crackling noise, as if air was present underneath, could be distinctly heard. Over this morbid expanse the integument had undergone striking changes. A marked lowering of the temperature of the skin was noted at this time. In patches it had a bronzed color, comparable in hue and density to the rind of ham. Intermediate to these hand-sized patches of pigmentation were irregular ecchymotic spots, and between these discolorations the normal hue of the skin was present, traversed by dark-blue lines of swollen, congested veins. The edematous and emphysematous condition of the skin ended in a well-defined margin. The perineal region was of a deep red, and edematous. Nausea was so great that scarcely any fluid could be retained, while the thirst was unquenchable. A small quantity of urine had been passed. He begged continually for hypodermic injections of morphine, which would for a short time steady his pulse and in a measure relieve him of the dyspnœa which intensified his sufferings very much. At noon the œdema and emphysema had extended to the hypogastric region, had invaded the left side and right gluteal region, and was rapidly increasing in every direction. The bronzed and ecchymotic patches developed coincidently with the œdema. The temperature in the axilla was 98⅕°. With the exception of a few short naps the patient had been without sleep since Monday night.

The condition of the patient in the evening was simply an intensification of that of noon. The greater

[1] Read at the first meeting of the American Association of Genito-Urinary Surgeons, at Lakewood, N. J., May 18, 1887.

part of the trunk and the right leg had been attacked, and the face, which all along had been pinched, became somewhat swollen. Amid these terrible sufferings the intellectual faculties of the man remained perfect. At this time his great restlessness, his agony, utter prostration, and dyspnœa were painful to behold. His unceasing appeals for death were piteous in the extreme. At 10 P.M. the axillary temperature registered 97° F., and the pulse so small and rapid that it was impossible to count it. His condition continued to grow worse until 7 A.M. of Thursday, eighty-seven hours after the operation, when he died in untold agony, in the full possession of his mental faculties, of failure of the heart's action. The corpse presented a horrible appearance, and emitted an intolerable, sickening stench. The head and neck were swollen beyond recognition. The scrotum was as large as a man's head, purple, gangrenous, and oozing. The body was nearly twice its normal size, and when tapped by a small instrument, such as a pencil, gave resonance similar to that of a drum. The bronze and ecchymotic patches had invaded the whole integument, and large bullæ, some distended with bloody serum, others ruptured and exuding a fetid fluid, were scattered over the trunk.

Though spoken of by Larrey in 1792, and again in 1836, and at different times described in a more or less imperfect manner by Martin de Bazas, 1836; Chassaignac, 1849; Maisonneuve, 1853; Velpeau, 1855; and Salleron in 1858, this affection was really not well known until 1870. It is to French surgeons, moreover, that we are indebted for the bulk of our knowledge concerning it. A multiplicity of names have been applied to it, many of them unprecise, while others, based on opinions as to its nature or upon individual symptoms, were more or less imperfect. The following list includes the chief titles: Emphysème gangréneux ou empoisonnement traumatique (Chassaignac), érysipèle bronzé (Velpeau), pneumohémie putride (Maisonneuve), gangrène foudroyante (Maisonneuve and Frèry), emphysème du moignon (Salleron), infection putride aiguë (Perrin), gangrena invadente (Bottini), septicémie gangréneuse aiguë (Morand), gangrène foudroyante traumatique (Jubin), œdème aigu purulent (Pirogoff), panphlegmon (Fischer), septicémie aiguë à forme gangréneuse (Terrillon), gangrène gallopante (Gosselin), gangrène gazeuse (Mollière), gangræna septica acutissima (Hueter), acute traumatic and spreading gangrene (W. Maccormac), acute spreading gangrene (Sydney Jones), and traumatic gangrene of many authors. Though so much has been written on this affection by so many observers, there is really but one systematic and exhaustive article on the subject, and that is written by a French surgeon of marine, Dr. Trifaud,[1] who, though he adopts the name given to the affection by Mollière, thinks that the expression septicéme gazeuse foudroyante is more exact. In this I fully agree with him. Trifaud's admirable study is based on one hundred and twenty-three cases, twelve of which were his own.

This disease occurs in greatest numbers among the wounded of armies and in the navy, and is particularly deadly in persons addicted to alcohol. It may have its point of departure in any solution of continuity exposed to the air, but seems to follow injuries of the leg rather than of the arm. Out of the one hundred and twenty-three cases collected by Trifaud it was found seventy-five times in wounds of the leg, and was more rapidly fatal where the wounds presented extensive anfractuosities. It always begins thus locally, and from the point affected spreads, and unless arrested by amputation involves the whole body, constituting one of the most terrible and deadly accidents known to surgery. While in most cases it appears in epidemic form in camps, ships of war, and crowded hospitals, it may also appear sporadically, as in the foregoing case, in a recent case at the St. Thomas Hospital,[1] London (Mr. Sydney Jones), and in one case in private practice, and another in hospital practice, both patients of my friend Dr. R. F. Weir. During the Crimean War, Salleron, out of sixty-five amputations, saw this form of septicæmia develop in fifty-eight cases within eight days, and seven times after the eighth day, while in Jubin's experience in the Hôtel Dieu, at Lyons, he observed its appearance in nine cases on the second day after traumatism. It rarely appears after pus-formation occurs in wounds. It is a singular fact that, while this affection was of frequent occurrence during the Crimean War, Salleron reporting sixty-four cases in six hundred and twenty-nine operations, during the Franco-German War of 1870 and 1871 French surgeons knew but little of it and regarded it as a form of hospital gangrene, and, further, that in 1881, when it became epidemic at the Hôtel Dieu, at Lyons, it was not seen in the equally crowded hospitals in Paris.

Septicémie gazeuse foudroyante has a clearly marked clinical history which, in the majority of cases, varies very little from the type-form; hence there is no necessity for errors in diagnosis. Beginning in the wound, it manifests itself by pain of varying severity. The parts look unhealthy, red, and swollen, and a thin, reddish, ichorous fluid exudes therefrom. Unless then arrested by ablation and thorough cauterization the disease inevitably extends. Then we find the painful and boggy point of departure, and very soon the œdema, the emphysema, the bronze and ecchymotic patches, the tortuous lines showing dark and swollen veins generally by continuity of tissue. In some cases, however, spots of the disease appear at points remote from the original focus, transmitted by the circulation. Soon we find the whole body invaded—its great distention, the formation of bullæ and oozing surfaces, and its rapid disintegration. French observers lean to the opinion that there are two forms of this affection—the one in comparison slow, pursuing much such a course as that observed in the foregoing case; the other extremely rapid, and fully meriting the adjective *foudroyante*, or its English equivalents, thundering, fulminating. In a case reported by Morand, the disease, beginning in the middle of the leg, spread to the base of the thigh during the eight or ten minutes necessary for anæsthesia and the preparation of instruments. According to my reading, however, it is only in the epidemic form on fields of battle and in crowded hospitals that this lightning-like course is observed. Unwholesome surroundings and debility from any cause undoubtedly tend toward such a result.

The subjective symptoms of this form of septicæmia are very constant and typical. They are quite fully portrayed in my details of the case. We find in a short time the thin, rapid, arhythmical pulse and the early appearing and increasing dyspnœa, which causes the patient so much suffering. Then comes the earthy pallor of the face, its pinched, anxious expression, with its deeply set eyes, surrounded by black rings. Besides there is the indescribable weakness, the restlessness and jactitation, and anxiety which increases to agony. The tongue becomes parched, the stomach more or less intolerant, though the thirst is severe and continuous. Sometimes there is bilious vomiting, sometimes diarrhœa, and at others constipation. And so do these symptoms become more intense until death relieves the sufferer, who usually is perfectly conscious to the last. During the first few hours of the disease the temperature may rise several degrees, but very soon it falls until several degrees below normal are reached.

In the light of our present knowledge of the rôle of micro-organisms in the causation of disease, the origin of this terrible affection is readily understood. At the time the foregoing case occurred we knew very little of these organisms, and less of their effects. It was quite natural, therefore, that my colleague and myself should look upon the complication as being caused by decomposition of

[1] Revue de Chirurgie, October, November, December, 1883.

[1] Lancet, February 4, 1887.

the tissues and fluids, and as being an anomalous form of septicæmia. It is the opinion of recent observers that this fulminating form of septicæmia is caused by a specific septic bacterium. Trifaud says that an absolute experimental demonstration of the rôle of the microbe of this form of gangrene has not as yet been made out. But certain facts point to it as the direct cause. These are, the constant presence of the microbe in the fluids of the body, and its extensive and rapid multiplication therein; the reproduction of the disease in animals by inoculation with the fluid containing this microbe, and the failure to reproduce it when the serum used has been previously filtered; and lastly, the negative fact that where perfect antisepsis is followed the disease has not been known to occur. I think, therefore, that a very strong case has been made in favor of the microbian origin of this deadly disease. We know as yet very little of a precise nature of the life-history and physical appearance of this bacterium. Trifaud thus describes it, and I prefer to use his own words and to let other observers make their own translation: "Cette bactérie est anatomiquement characterisée par un bâtonnet long et grêle, présentant à l'une ou aux deux extrémités un nucléole; elle possède des mouvements nombreux et variés; elle monte, descend, tournoie dans le liquide de préparation au milieu de nombreux corps lenticulaires et de spores."

The bacterian origin of this affection being conceded, the practical application of the fact forcibly suggests itself. When we know that such a terrible and deadly scourge as this disease may originate in so simple a lesion as a leech-bite, and in all wounds, traumatic or surgical, our duty to use all intelligent and conservative measures toward thorough antisepsis is plainly and forcibly indicated.

As to the origin of the disease in the case which I have detailed, I am constrained to say that I think the morbific agent was carried to the deep urethra either by the urethrotome or the sound. I must here add that the operator was a man thoroughly versed in all genito-urinary operations and one of the most careful and painstaking of men in all details incident to an operation and as to care and cleanliness of instruments.

Owing to the rapidity of decomposition, in all cases of death from this form of septicæmia autopsies must be made immediately. It is then found that the disease has involved the cellular tissue, which is softened and permeated by a reddish fetid fluid and by gas, which is generated in large quantities after death. There is also a diffluent condition of the blood, but pus and metastatic abscesses are never found.

Trifaud very pertinently asks whether many cases of death from supposed poisoned projectiles were not those of septicémie gazeuse foudroyante.

40 West Twenty-first Street.

Mortality in Public Lying-in Hospitals of Germany.—Döhrn, in *Zeitsch. f. Geb. und Gyn.*, p. 121, 1886, draws attention to the great diminution in the mortality of lying-in women which has taken place in the above-mentioned establishments since the introduction of antiseptics. He selected the period of 1874–83, since in 1874 antiseptics were scarcely used anywhere, while in 1883 they had become very general. The total number of cases of labor was 104,287, and 1,429 women, or 1.37 per cent., died. The vast improvement indicated by this percentage will be clear on comparison with the statistics of previous years. Thus, in 1866, Lefort found the average mortality in the lying-in hospitals to be 3.4 per cent., while Winckel, in 1869, calculated the mortality on 500,000 births to be 3 per cent. Even this great improvement, however, in lying-in institutions leaves their mortality far behind that of women attended in private practice; in the latter the percentage of deaths is only 0.6 to 0.7 per cent. Various influences contribute in bringing about this result.

ON TEMPORARY OVERSTRAIN OF THE BLADDER, PRODUCING LOCALISED ATONY AND CHRONIC RETENTION OF URINE.[1]

By F. N. OTIS, M.D.,

Clinical Professor of Genito Urinary Diseases in the College of Physicians and Surgeons, New York.

Long continued obstruction to urination, as through organic stricture or enlargement of the prostate gland, while often causing a general thickening and rigidity of the bladder-walls, is recognized as capable, in certain cases, of producing a mechanical overstrain and consequent thinning of the muscular structure of the bladder, diminishing its contractile power, and thus preventing, to a greater or less extent, the complete discharge of urine from the bladder by voluntary effort.

This condition is called atony or inertia of the bladder, to distinguish it from the paresis or paralysis of the bladder which is dependent upon nerve-lesions.

While, however, atony of the bladder, as a rule, is due to long-continued urinary obstruction, and is chiefly found in elderly persons whose muscular structures are already more or less enervated, yet this is a form of this trouble which results from a sudden overstrain through even a single attack of retention, at any period of adult life, and independent of any organic obstruction. Such an attack may be the result of spasmodic stricture caused by irritation of the muscular urethra through a contracted meatus urinarius or a stricture of the urethra (even though slightly narrowing its lumen), or through inflamed hemorrhoids in persons otherwise healthy. It may occur through temporary loss of sensibility, as from the effects of alcohol or narcotics; or during the course of a low fever; or from a convulsion or any nervous shock; also from disregard of desire to urinate, or from sexual irritation or excess. A retention from any cause may, within the space of even a few hours, produce an overstrain of the muscular structures of the bladder, causing entire loss of the voluntary power of urination; a loss which, especially if occurring in advanced life, not infrequently necessitates the use of the catheter for the passage of every drop of urine during the remainder of the patient's lifetime.

The frequency with which such accidents as the foregoing have been brought to my notice has impressed me with the importance of, if possible, a greater solicitude in regard to the condition of the bladder in all persons who have been for any period insensible from any involuntary cause, or who have experienced any decided nervous shock, or who are the subject of any urinary difficulties.

I desire on this occasion to call attention to a few cases in my own experience bearing on this point.

In the first place, in order to illustrate the cause which I believe to be the most frequent in producing urinary retention, and thus atony of the bladder, to a greater or less extent, I will cite a case reported to me by the late Prof. R. W. Pease, of Syracuse, some time since:

General H——, aged sixty-five, previously free from all urinary trouble, while walking was seized with a desire to urinate, and on attempting to do so was quite unable to pass a drop. Dr. Pease was called some few hours after, and attempted to draw his urine by means of a flexible catheter, No. 20 (F.); the size of the meatus passed the instrument readily as far as the bulbo-membranous junction and there it was arrested. Various sizes, soft and metallic, were used with the same result. A consultation was called, in which several prominent physicians and surgeons of Syracuse took part. The patient was etherized, and efforts were made with various instruments, from No. 20 (F.) to the filiform size, to enter the bladder, but without success. There was no enlargement of the prostate. As the bladder was then considerably above

[1] Read at the meeting of the Association of Genito-Urinary Surgeons of America, at Lakewood, N. J., May 18, 1887.

the pubis, it was determined to relieve it by aspiration. Just as the aspirating-needle was about to be inserted, mention was made of the fact that such cases were claimed by Dr. Otis to be sometimes due to a spasm of the compressor urethræ muscle, caused by a contracted meatus urinarius. The meatus was forthwith divided, and the largest catheter available (30), of the French scale, was introduced, and passed readily into the bladder. As the doctor expressed it, "It slid into the bladder like a boy sliding down an ice-covered hill."

Professor Alfred C. Post relates the following:

In March, 1884, he saw in consultation a lawyer, aged sixty-two, with a retention of urine. There was a history of several previous attacks, which were relieved by the introduction of a small catheter into the membranous portion of the urethra. The urine flowed at this point, but the instrument could not be passed into the bladder. The trouble was believed to be caused by senile enlargement of the the prostate. Examination by the rectum showed that there was no such enlargement. The orifice of the urethra was contracted to 15 of the French scale. Dr. Post incised it and passed 24, the largest catheter he then had, easily into the bladder and relieved the retention. On the following day he incised the orifice still farther, and passed a solid sound, No. 33, with ease. The patient regained at once the power of emptying the bladder voluntarily, and, after a period of several months, was found to have retained this power.

Mr. C——, aged seventy-two, referred to me by Dr. C——, of Ohio. History of difficulty of urination for two years previously. His trouble was assumed to be from prostatic hypertrophy, and the use of the catheter was commenced, using it twice in the twenty-four hours. Twice within the next few months he had a complete retention of urine for a day, with much pain; since that time was able to void but a very small quantity of urine voluntarily. Examination showed but slight prostatic enlargement. Urine increased at will through the catheter. Highly ammoniacal and purulent. Attempts at voluntary urination frequent, with pain in glans penis at close. Examination of the bladder failed to detect stone. Examination of urethra showed a normal calibre of 38, a narrowing at 4 inches of 5 mm., and at 3 inches one of 8 mm., also a narrowing at the orifice to 26; these strictures were divided to 38, and 32 solid sound passed into the bladder.

The immediate result of the operation was slight constitutional disturbance, lasting forty-eight hours, frequent necessity of use of catheter every hour or two for twenty-four hours, then a sudden improvement—intervals, six to eight hours; complete loss of pain at glans penis after voluntary urination and gradual increase of quantity voided. On the seventh day he emptied his bladder voluntarily. He went home on the tenth day with the understanding that the occasional use of the catheter should be continued until the power of emptying the bladder was fully restored. A recent letter from his physician informs me that the use of the catheter is still required to completely empty the bladder, but that there has been no retention; the pain in the glans penis, originally relieved by the operation, had returned. In this case, on account of the age of the patient, 32 sound only was introduced through the deep urethra after operation; a full distension at this point would probably have produced more permanent results, although increasing the risk of constitutional disturbance.

Mr. F——, a gentleman of seventy, suffered with posterior spinal sclerosis for several years, but was able to walk about his apartments, though with difficulty. He lived alone, declining to have any personal attendant. One morning in January last was troubled with slight diarrhœa; he took an accidental overdose of Squibb's tincture of opium. During the narcosis which followed he had a retention of urine of from twelve to eighteen hours' duration; previously to this he had no urinary difficulty. The bladder was gradually emptied by catheter, during the next twenty-four hours from three to four pints being withdrawn. The use of the catheter was continued for twenty-four hours longer, when, having completely recovered from his narcosis, it was found that he was unable to pass a drop of urine voluntarily. He was found not to have any prostate enlargement. This complete retention continued, relieved only by catheter, for the next two weeks, requiring its passage every two hours, day and night, when he regained voluntary power of urination to the extent of passing an ounce or two while in the closet. As a 24 F. catheter had been easily passed, no examination was made for stricture. This was now done, resulting in finding several points of contraction, strictures of large calibre, of 13 mm. (27 F.) in a normal urethra of 40; meatus, 32 F. These were divided and 40 sound passed through the strictures, 38 into bladder. There was not the least constitutional reaction. There was an immediate increase in desire to urinate, requiring now the use of the catheter every hour or two for about a week, caused by a slight cystitis of the vesical neck. This, however, yielded to ordinary measures and he began to urinate voluntarily at irregular intervals, and requiring the passage of the catheter less and less frequently, until at the end of a month he would go five and six hours without the necessity of emptying his bladder. His general health continued excellent, his mental condition improved in a very marked degree, and even his power of locomotion was increased, but his inability to empty his bladder completely continued, having habitually from two to four ounces of residuum after every voluntary micturition. In the meantime ergot, strychnia, iron, cold-water injections into the bladder, douches, etc., had been administered, without apparently affecting the local difficulty in any way, and the case continues in about the same condition to-day.

Another case was one where a slight paresis of twenty years' standing and of central origin complicated the atonic condition. The patient was able to pass the urine voluntarily, with the exception of an ounce or two of residuum. About a month since a uræmic convulsion occurred. Two hours preceding this the urine had been drawn by catheter. Two hours after, when I saw the case, the bladder was prominent above the pubis and I drew off twenty-three ounces of urine of a specific gravity of 1.005. This retention was followed by a complete loss of the voluntary power of urination, which continued for several days.

In May, 1885, Mr. M——, was referred to me by Dr. B. of Canada, with complete loss of the power of voluntary urination. His history was as follows: Three years ago, having had no previous difficulty in urination, he, on one occasion, forgot to void his urine on going to bed. Attempting it on the following morning, he found himself unable to pass a drop. A catheter was introduced by his physician without much difficulty, and a large amount of urine drawn off. This loss of power continued. He was obliged to learn the use of the catheter. From this time, in spite of much treatment by electricity, strychnia, mineral waters, and a thorough course of mercury (as syphilis was suspected by a physician at one of the springs which he visited), he went on without improvement in his urinary function. After a year he had an attack of cystitis, lasting some five weeks, during which his power of urination returned and he was compelled at times to urinate every half-hour. When this cystitis passed off, however, his ability to urinate also departed and he remained in this condition absolutely without being able to pass a drop of urine voluntarily, and was obliged to use a catheter on an average of once every few hours up to the time when he came under my observation, fully two years from the date of his first attack.

The general health of the patient was enfeebled. He was the subject of great mental depression, and was much of the time absorbed in the contemplation of this bladder trouble, but he suffered no pain.

On examination, patient passed a No. 20 gum-elastic

catheter with ease, although at times there was some difficulty from urethral spasm. The urine drawn was clear. There was apparently no atony of the bladder, as the urine was propelled through the catheter with force and was promptly increased at will. There was no prostatic enlargement, and nothing abnormal could be detected through examination of the bladder by metallic sounds or bimanual touch. Penis, 3¼ inches in circumference. By urethrometer, 32 mm; at bulb and anterior two inches then there was a narrowing to 25 mm. (7 mm.), for half an inch anterior to which the urethra was contracted at several points from three to five millimetres; narrowing at the meatus to 28 mm.

The presence of more or less stricture had been recognized by his physician, and as all measures used had failed to afford relief, he was referred to me for any operation which might promise to restore his urinary function.

The presence of strictures of large calibre, as in the present instance, had been associated in my experience, in many cases, with repeated retention of urine of a temporary character, in several instances producing more or less atony of the bladder. Here, however, the muscular structures appeared not to have been impaired.

I had seen and reported cases where long-continued partial obstruction to voluntary urination was caused by the reflex influence of strictures of large calibre, as proved by the immediate and permanent relief afforded by their division and the introduction of a full-sized sound, one a notable instance where a retention of three years' standing (the bladder habitually containing two pints of urine) was relieved in a similar manner; but in all the cases there was either inability to pass any instrument through the membranous urethra, or to such a degree as to warrant the assumption that the difficulty, if not organic stricture, was dependent upon spasmodic closure of this portion of the urethra from reflex irritation. In this case, however, while there was, from time to time, much annoyance from such cause during catheterization, yet, as a rule, a 20 F. catheter was readily passed into the bladder, while at no time could a drop of urine be passed voluntarily.

The complete removal of these strictures was advised, with the distinct understanding that while a complete restoration of the urethra to its normal calibre might restore the urinary function, yet it was not improbable that some condition at the vesical neck was the chief cause of the trouble, and if not relieved by the internal urethrotomy a digital exploration of the bladder through perineal section would be required.

On June 1, 1885, Mr. M—— was etherized, his strictures thoroughly divided by dilating urethrotomy, and a No. 32 solid steel sound passed, without force, well into the bladder. The urine was drawn by catheter, as usual, and a No. 32 sound was passed through the urethra as far as the bulb every other day for a week after the operation. A few drops of urine had, from time to time, passed involuntarily during a passage from the bowels after the third or fourth day. On the morning of the eighth day, the urine having been allowed to accumulate until some distention of the bladder was recognized, the attempt to urinate was made; a few drops of urine only responded. This, however, gave a distinct sense of relief, but the remainder required to be drawn with the catheter. Although disappointed at the result, the patient, whose constant brooding over his trouble amounted almost to a monomania, was comforted by a rapid improvement in his general health and in his mental condition, which began immediately after the operation. The ability to void a few drops of water while at stool was the only approach to an improvement in the urinary function which had been attained by the operative measures; and it was evident that the cause was not in the urethra, but in the bladder. It was determined, however, to delay any further operative measures until the autumn, when, if the difficulty still remained, and his general condition seemed to warrant it, the digital exploration of the bladder through the perineum should be made.

Mr. M—— returned early in October, four months after, in excellent condition; but he had had no voluntary passage of urine, except the few drops when his bowels were moved. His sexual powers, which had been greatly impaired before the operation, were fully restored, and he had only the necessity of passing the catheter once in six hours, as against once in four hours previous to the urethrotomy. His urine was examined and found to be normal.

On October 9th Mr. M—— was etherized and the perineal section performed, Dr. L. B. Bangs, Dr. Norris, and Dr. W. K. Otis assisting. Introducing my finger through the perineal opening, I was unable to detect any abnormal condition in the prostate or in the bladder, which was, by means of bimanual touch, thoroughly exposed in every part. The only part that even suggested any further interference was an unusual tightness at the vesical orifice, notwithstanding the thorough dilatation which it had undergone, and this was not, however, considered to require any further operative measures. A tube was introduced and retained for the next five days, when, on removing it, no urine passed through the sound or through the penis. Complete retention occurred, which was relieved by the passage of a catheter through the wound, twelve ounces of urine being withdrawn. With a Davidson's syringe I subsequently introduced water up to fourteen ounces through the tube, without producing any desire to urinate, or any tendency to flow out through the wound or urethra. My urethrometer was introduced through the perineal opening into the bladder, turned up to 45, and withdrawn without resistance. It was then evident that a faulty action of the muscles of the vesical orifice had in some way produced the obstruction. On the previous exploration no organic obstruction like a bar could be detected. It was determined to make a further digital examination under the local influence of cocaine. This was accomplished without difficulty, and with but little pain; nothing new was recognized—the slight constriction at the vesical orifice previously noted was again detected, and it was determined to incise the constriction at that point. This was effected on introducing a straight, blunt bistoury through the perineal wound and dividing the tissue, guided by a finger in the rectum; until, upon a reintroduction of the finger into the bladder, no sense of constriction could be felt at the orifice. The tube was then replaced. There was no constitutional reaction. Forty-eight hours after the operation, for the first time since his original retention, two years previously, Mr. M—— felt a natural desire to urinate, and a few drops of urine were passed through the penis. During the entire period since the commencement of his trouble the call to urinate was only through a sense of distention, which, if not responded to, was soon followed by a pain over the pelvis. On removal of the tube, urine now leaked through the perineal opening.

The day following, October 21st, the patient passed with natural sensation ten ounces of urine through the penis. From this time he passed his urine for a few days about equally through the perineal opening and through the penis, until after a couple of weeks, the perineal wound rapidly healing, the introduction of a catheter was again required, as he could not fully empty his bladder voluntarily, having always from two to four ounces of residual urine. He was advised not to make any straining effort, but in order to completely prevent this he was to use the catheter regularly for at least three or four months. Iron and strychnia internally. By November 30th he went to his home in fair general condition, using his catheter faithfully, but mentally much disturbed that his hopes of being able to void all his urine voluntarily were indefinitely deferred.

I heard nothing from the case until December, 1886, a little over a year after, when I received a letter from

Dr. B. stating that our patient had recovered completely from his urinary troubles and was in excellent health and spirits. He went along worrying and using his catheter for several months after returning home, getting finally into a state of hypochondriasis—complaining of inability to walk and of various discomforts. His physician sent him abroad for a few months, but he returned in the same condition. Being then unable to find any real cause for his alleged suffering, his physician then insisted upon his getting in his carriage and driving about, although the temperature was considerably below zero. He at once improved. Finally he was induced to ride on horseback, and within a very short period the doctor states that our patient had found himself able to fully empty his bladder voluntarily, and from that day to the present has been able to do so, as was reported to me by letter dated April 22, 1886, thus, "Mr. D. is as well as he ever was in his life."

The manner in which the original retention of urine occurred in the foregoing case points clearly, it appears to me, to spasmodic closure of the membranous urethra as the immediate cause, apparently due to the presence of anterior strictures of large calibre. Speaking of this condition, Esmarch says:[1] "My experience enables me to state that spasm of the urethra occurs frequently, and is often, if not principally, the cause of retention of urine."

The direct result of the retention was not to cause a general atony of the bladder, but a disability of the muscular structures in the vicinity of the vesical neck alone.

The chief diagnostic point in the recognition of atony of the bladder, according to Sir Henry Thompson, is the "diminished power of discharging the urine after a catheter has been placed in the bladder." In this case the power to increase the stream under such circumstances was normal, except when the bladder was nearly emptied. A localized instead of a general atony was present, and under conditions that would seem to indicate that this is the form of accident which most commonly occurs when a sudden temporary over-strain is the recognized cause of interference with voluntary micturition.

The contents of the full bladder, when acted upon by the detrusor muscle as a whole, reinforced by the diaphragmatic and abdominal muscles, appears to bring the greater force to bear on the bas-fonde; and if the pressure be so great as to cause over-distention, it would be most likely to occur in the greatest degree at this point.

According to Esmarch, "the outermost longitudinal layer of the detrusor muscle passes vertically into the prostatic ring, and consequently opens the ring as soon as the detrusor contracts over the liquid ball within the bladder. The urine now enters through the prostate into the membranous portion, etc." Here, however, the condition which we call spasmodic contraction of this portion of the urethra arrests the progress of the urine, and the chief strain then falls upon the muscular fibres, which in a normal condition serve to open the vesical orifice. These, too, being attached vertically to that orifice, the force would act directly upon it, and here the atony would be most likely to occur, causing a more or less permanent disability of the emptying power of the bladder. The anterior portion of the detrusor, not having been subjected to such a degree of over-strain, might by its superior tonicity cause a change in the situation of the orifice so as to form an additional barrier to the outflow of urine, which would be increased by voluntary effort to empty the bladder. The operation of incising the vesical neck, as in the case reported, it appears to me, would serve to correct in some degree the disturbed muscular relations of the parts; but chiefly to diminish the resistance of the so-called sphincter vesicæ, and thus make the action of the detrusor more effective, both resulting together in an immediate partial restoration of the function of urination, which as the detrusor gradually gained strength through the rest afforded by the long-continued catheterization, finally brought about a restoration of the voluntary power of emptying the bladder.

The suggestions which, in reviewing the foregoing cases, appear to me most salient are:

1. The necessity of appreciating the fact that slight urethral contractions, at any point from the meatus to the bulb, are a possible cause of retention of urine, through reflex irritation, and should enter into the consideration of such cases, especially in elderly subjects, whenever such contractions are known to exist.

2. The importance of an early recognition and relief of an acute retention by catheterization.

3. That localized atony at the base of the bladder may be present in sufficient degree to wholly prevent voluntary urination, while the contractile power of the superior portion remains practically undiminished.

4. The understanding that the failure to relieve, through the removal of sources of reflex irritation which might be considered sufficient to produce and perpetuate the spasm of the muscular urethra, should suggest the possible relief, even in long-standing cases, which may be afforded by an incision of the vesical neck.

5. That any local or general treatment which may be adopted independently of the removal of the cause upon which it depends is of but little avail for permanent cure.

6. That a period of several months of freedom from the cause producing it must not be considered too long to wait for recovery from over-strain or atony of the bladder.

A PLEA FOR THE MORE GENERAL USE OF THE NITRATE OF SILVER IN THE DEEP URETHRA, WITH AN IMPROVED INSTRUMENT FOR ITS APPLICATION.[1]

By E. L. KEYES, M.D.,

NEW YORK.

Inflammatory troubles and irritative disturbances about the deep urethra and the neck of the bladder are to the patient disproportionately offensive, if the subjective annoyance is weighed against the actual gravity of the affection, and to the surgeon often unsatisfactory, because the ordinary methods of treatment are usually slow, uncertain, and at times totally ineffective. I think the above statement is not too broadly drawn.

Our general rules of treatment are, for irritative disorders, alkalies, diluents, diet, the sound, moderate anodynes, the correction of sexual irregularities, and the division of points of narrowness along the anterior urethra. For acute and chronic inflammatory and suppurative disorders we use alkalies, diluents, diet, rest, stronger anodynes, sometimes the balsams internally, and perhaps blisters to the perineum. Local treatment, except the sound, is considered totally ineffective in irritative disorders; it has to be used with great caution in subacute inflammatory conditions, and its employment is commonly interdicted in the acute stages of a given disorder—gonorrhœal or otherwise.

In many of these conditions, and their number is very great, and in others of a sexual sort, such as pollution, spermatorrhœa, lack of sexual vigor, nervous impotence, imperfect erectile capacity, and the like, I have of late years derived such signal advantage from the use of nitrate of silver in the deep urethra, that I feel impelled to lay an outline of the facts before you and to show the instrument upon which I have come entirely to depend. I think I may say that in customary office-practice at the present day my average employment of the nitrate of silver in the deep urethra is greater than the use of any other one single means of treatment of urethral disease, and my success with the method, although, of course, far

[1] Read at the meeting of the American Association of Genito-Urinary Surgeons, May 17, 1887.

from universal, is greater than that which I have derived from any other one means in the management of similar disorders.

I think it necessary to make this statement because I find a wide-spread fear in the profession in America regarding the use of nitrate of silver in the urethra. No less than two members of this Association have declined to use deep urethral nitrate of silver injections upon patients in whom I had already successfully instituted a course of treatment by that means, objecting on the ground of a fear of present or future harm to the patient, if the course were followed out, and in each instance they have advised the patient against it. This same experience at the hands of other surgeons outside of this Association is to me a matter of very common occurrence.

I may state here that I have been almost constantly using the nitrate of silver in the deep urethra for the past four years. I believe it safe to estimate that I have administered no less than three thousand injections upon private patients in my office in that time. I have never seen any harm come of it more than a temporary local irritation lasting a few days, occasionally a show of blood, and one very moderate attack of epididymitis, which possibly was produced by one of my earlier injections. At the hands of my assistants I have seen one case of cystitis and two of swelled testicle caused by it, while they (the doctors) were yet young and inexperienced in the use of the method. These remarks apply only to the last few years, since I have used the instrument of Ultzmann and the one of my own construction, which is a modification of Ultzmann's instrument.

In former days, when I used nitrate of silver injections with old-fashioned instruments I caused considerable havoc and probably more inflammatory disturbance than I cured, so that I gave up the use of deep urethral medication almost absolutely, and it is only upon taking it up again with more knowledge, more care, more sense, I hope, and better instruments, that I have obtained results of what I consider great excellence. I have never gone above the strength of a ten per cent. solution—forty-eight grains to the ounce—except in one instance of nocturnal pollution, and I rarely use a solution stronger than ten grains to the ounce, and usually a much weaker one.

The maladies in which I have had the greatest success are: Gonorrhœal cystitis, acute and chronic; ordinary irritability of the bladder; acute or chronic suppurative inflammation of the deep urethra, with or without surface prostatitis; double relapsing epididymitis, due to the foregoing cause; tendency to relapsing cystitis in connection with large prostate; prostatorrhœa; spermatorrhœa, with abnormal deep urethral sensations, often accompanied by oxaluria, depression, melancholia, etc.; nocturnal pollutions, with apparent lack of sexual vigor; nervous impotence. These cases are sometimes rebellious to this as to all other treatments.

It is proper to state that the treatment does not suit all cases of each of these maladies. On the contrary, cases occasionally turn up which are not at all benefited by this treatment, and even cases which are positively harmed by it. Their number is very small. I never decide to use the treatment in a given case until I have made one, possibly two, tentative injections. If they are well borne and no disturbance follows, even if no good results, I push the treatment, still tentatively. If good is to come of it the fact is apparent after three or four injections, sometimes after the first. The method I employ is always the same. It is based upon a theory which I shall first set forth.

The instrument I use is like Ultzmann's in being open only at its tip. I have seen other instruments so constructed (that is, with one opening only, and that at the tip), but this form, as you know, is not the usual one, most instruments being perforated with a certain number of minute holes or slits for a given distance from the tip, or terminating in a bulb which is variously perforated.

Ultzmann's instrument has, in my opinion, only four defects—the length of the shaft, ample in the vast majority of cases, is sometimes scant in big-bellied old men; the mark upon the hard rubber to show the direction of the tip is not definite enough; the coupling between the syringe proper and the long nozzle is unnecessary, likely to get out of order, and liable to cause the operator to soil his hands; the syringe is flimsy, constantly becoming uncemented at its lower junction. Outside of these minor defects, I consider Ultzmann's syringe perfect.

My own changes have been to meet these requirements. The shaft is seven inches long, with moderately

long curve; the size, 13 French. I have a shorter instrument with different curve for young, small, thin persons. The whole instrument is metal and solidly constructed in a single piece, making leakage impossible and a giving way of any part of the syringe out of the question, unless the piston-packing dries or the glass breaks. I have wide lateral wings, which greatly facilitate the easy use of the instrument, and a pronounced indicator to show the direction of the curve. The metal out of which the long nozzle is made should be pure silver—to prevent decomposition of the solution of nitrate used, which otherwise continues to take place for a long time, until the inside of the tube has become thoroughly coated with the black precipitate, which is at first thrown down if the tube is made of German silver. This coating is liable to flake off in German-silver instruments and clog the tube. The syringe proper may be as well made of German silver. The cost of the pure silver tube is moderate.

The theory upon which I have used the instrument is this. Deep urethral inflammation, when it gets past the hole in the triangular ligament, does not yield to injections of the anterior urethra, because the injected fluid does not penetrate deeply enough. The same power of the cut-off muscles which prevents urine from getting out of the bladder (against one's will) also prevents fluids thrown from the outside from entering the bladder, unless considerable force is used, a violence paid for in some instances by inflammatory reaction. But the passage of an instrument, even very gently, through the deep urethra is not devoid of risk, and the less deeply it is inserted the better for the patient. With an instrument of this kind it is only necessary to simply enter the front part of the membranous urethra. Two or three minims of solution there deposited diffuse themselves backward over the entire membranous and a portion of the prostatic urethra, and do as much good, in my opinion, as if a quart had been used, and far less harm in the way of setting up irritative and inflammatory reaction or the possibility of exciting disturbing complications.

This is the amount of injected fluid used, and the position in which I place it in all the conditions treated, except gonorrhœal (or other suppurative) cystitis of the neck of the bladder. In the latter instance, I inject in the same way from just barely within the beginning of the membranous urethra, but I use more of the injected fluid, generally five minims, occasionally even a little more. This amount diffuses itself backward, and appears to do all the good possible, with no harm. This I consider to be the great advantage of using a syringe open at the tip. By its employment and simply introducing it just within the membranous urethra the whole bladder may be injected, if it is so desired, or as much or as little of the very seat and focus of the irritative part of all the disorders situated in this region, namely, the middle and back parts of the membranous urethra. And this can be

done without passing any instrument into this middle and back part of the membranous urethra, the position of greatest danger, in my opinion.

In treating neuralgic, irritative, and deep urethral inflammatory disorders, I endeavor to inject while the patient holds water in his bladder, preferring to have no traces of urine at the point to be injected (on account of the decomposition of the nitrate solution which it causes). In gonorrhœal cystitis when there is much pus, I prefer to ask the patient first to urinate, so as to clear away the pus and leave the bladder empty, that a drop or two of the injected liquid may reach the bladder just at the urethral orifice. The greater amount of injected fluid in these cases more than compensates the decomposing action of the urine. Under no circumstances do I first wash out either the urethra or the bladder.

The seat of greatest sensitiveness about the neck of the bladder, and the focus of the disease in gonorrhœal cystitis, is the back part of the membranous urethra. It is at this point that the ordinary sensation of a desire to urinate is experienced by the patient; it is here that the same sensation is called out during the passage of a sound. This sensation is not felt at the beginning of the membranous urethra. As the nozzle of the syringe enters this region no complaint of a desire to urinate is usually made. In inflamed conditions it is made. In gonorrhœal cystitis and in the other conditions I have mentioned, a few drops of a nitrate of silver solution, placed accurately in the membranous urethra, in many instances promptly turns the whole course of the malady, and even in grave cases of serious inflammatory disease it often comforts when it does not cure.

The treatment often fails in irritability of the vesical neck due to enlarged prostate; it often seems to fail in directly influencing deep urethral spasm; and it appears to aggravate cancerous and tubercular trouble at the neck of the bladder. Guyon [1] has observed this same peculiarity. Indeed, he has gone so far as to consider that failure of nitrate of silver to do good is a differential diagnostic point between cystitis of the neck due to cancer or tubercle and the same affection dependent upon other causes. My own experience teaches me to doubt the value of the method when the cystitis is due to traumatic causes, notably the cystitis following sometimes upon internal urethrotomy. The method is most often effective where the surface tissues only are involved, there being no considerable thickening, inflammatory or otherwise, about the urethra. I make a fresh solution for each case injected—using a standard ten per cent. solution, and diluting it suitably in a minim-glass. I generally commence at about one grain to the ounce, and work up, making the intervals two to five days longer as the injections grow stronger.

The desire to urinate usually comes on sharply a few moments after the injection is placed. I allow patients to yield to this, but urge them to hold back the second call as long as is reasonably possible, and particularly not to strain after urinating.

The treatment of deep urethral and vesical troubles by instillation of the nitrate of silver and by a method somewhat similar to the one I have described, but, I believe, less gentle and more liable to be attended by risks, has for some years been advocated in Vienna by Ultzmann, his admirably concise and practical ideas being set forth in this country in a translation of his little monograph on "Pyuria" by W. B. Platt,[2] of Baltimore, and for fifteen or twenty years in France, by Guyon, who uses a bulbous-headed, soft bougie for his instillations, the perforations for the passage of the fluid being behind the shoulder of the bulb. His ideas about the efficacy of the treatment and the manner of using the bulb have been quite recently set forth, both for the treatment of disease in the urethra and the neck of the bladder, in the *Annales des Maladies des Organes Génito urinaires.*[1]

I have experimented with other substances for deep urethral injection, such as hydrastin, sulphate of zinc, permanganate of zinc, glycerole of tannin, hydrochlorate of cocaine, sulphate of copper, but I have as yet little to say in favor of any substance except the nitrate of silver.

I append the short history of a few illustrative cases, some of the best and most typical out of many examples, in justification of what is written above:

Case I. *Acute gonorrhœal cystitis.*—In November, 1884, a young man, aged twenty-eight, acquired a gonorrhœa, for which his physician administered injections. In a few days acute bladder-symptoms set in. At the end of the fourth week I was called, to find the patient in a pitiable condition, pale, sleepless, depressed, thin, without power or inclination to eat, taking herb-infusions, alkalies, and twelve grains of opium a day, urinating every half hour, night and day, a mixture of urine, pus, and blood, with an intensity of pain following the act which it was distressing to contemplate.

I cut down the opium at once, administering a hypodermic injection in its place, and a deep urethral injection of nitrate of silver, gr. iij. to ʒ j., put the patient on a milk-diet, and ordered a cathartic. A few hours after the first injection improvement commenced. Ten injections were given at intervals varying from two to five days, and at strengths varying from two to five grains to the ounce. Improvement was uninterruptedly continuous from the first injection, and at the end of the fourth week the patient reported at the office, well, with perfectly clear urine. This is the best result I believe I have ever attained. The patient was so ill that his friends confidently expected him to die. His recovery was brilliantly prompt and perfect, and his bladder has remained sound ever since.

Case II. *Subacute gonorrhœal cystitis.*—A young man, aged twenty-three, came to my office, March 27, 1885, complaining of frequent urination, with pain during and after the act. He had been suffering for four weeks, in spite of treatment and the use of opium. His symptoms began shortly after the commencement of a gonorrhœa in the shape of urgency of urination with pain and the appearance of bright blood after the urinary act. The urine was thick with pus. In my office I injected the deep urethra of this patient with a solution of nitrate of silver two grains to the ounce. After three days I used a five-grain solution, three days later a solution of seven and a half grains, in a week a ten-grain solution, and at the next visit the patient reported himself practically well, urinating only four times in the twenty-four hours. This case also was admirably prompt in its response to treatment.

Both these cases are exceptionally good ones. I do not cite them as average specimens.

Case. III. *Irritability of the bladder.*—A gentleman, aged thirty-four, consulted me in October, 1882, for frequent and painful urination, night and day. He had to get up twice at night, and was tormented excessively by day at times; at other times his intervals of urination were nearly normal. Exercise and fatigue, nervous worry, and bad weather, all aggravated his trouble. He was married, and of temperate habits. His urine was acid, 1.027, contained a little pus, no blood, and enormous quantities of crystals of the oxalate of lime. His urethra was ample, except for a linear stricture at three-fourths of an inch, admitting 15 F., with difficulty. The deep urethra was exquisitely sensitive to the sound.

I cut the anterior urethra to 30 F., and five months later the patient reported great improvement, but he was not satisfactorily well, and such improvement as he had was ascribed rather to passing instruments through

[1] Annales des Mal. des Org. Génito-urinaires, vi., p. 345, June, 1884.
[2] New York, D. Appleton & Co., 1884.

[1] 1883, i. i., p. 613; and 1884, i., iii., p. 330.

the membranous urethra than to the urethrotomy. He suffered occasional relapses, in one of which, in October, 1885, I injected his deep urethra with nitrate of silver three times at intervals of three days, once with a five-grain, once with a six-grain, and once with a seven-and-a-half-grain solution.

This entirely relieved him, and he stated that he never had had anything do him so much good. He remained well for seven months, when overwork and mental worry, in the spring-time, caused slight relapse, which was again at once relieved by a six-grain solution. This was a year ago. The patient returned to his home in the country, and I have not seen him since.

This patient was essentially neurotic, oxaluric, overworked, over-anxious, and I have on that account selected him as an illustration. His relapses are accounted for by his nervous peculiarities. The relief afforded by the treatment in his case was most striking. I might describe a number of ordinary cases of common vesical irritability, but space does not allow. All are not cured by this treatment; a few cases are not helped at all; but most cases are materially relieved; many are cured.

Case IV. *Acute deep urethral inflammation.*—In November, 1886, a youth, aged nineteen, got into a serious condition of general urethral inflammation along the entire length of the canal. The discharge anteriorly had been suppressed by irrigation, so that the deep urethra suffered mainly. Indeed, the bladder became moderately involved, so that for a few days there was urgency and precipitancy of urination, blood once, and always a considerable amount of pus in the urine. The bladder symptoms moderated promptly under deep urethral nitrate of silver injections—from five to twelve grains to the ounce—but the flow of pus forward continued, the meatus was puffed up and livid, the frenum and foreskin œdematous, distress was complained off in the perineum, and the urine was loaded with pus, although the symptoms of cystitis had ceased.

This case was obstinate, but yielded entirely to deep urethral injections, varying from three to twelve grains to the ounce, at intervals of about five days, continued somewhat over a month. Poland water was used freely, a mild anterior injection which the patient used himself, and a little balsamic medication. The urine became as clear and sparkling as possible, and all urethral discharge—even the little shreds of pus in the urine—totally disappeared.

Case V. *Chronic deep urethral inflammation.*—A gentleman, aged thirty-five, came to me in November, 1885, complaining of gleet. Eight years before, for a persistent discharge after gonorrhœa, a surgeon had cut his orifice, and afterward had cut him for two alleged strictures of large calibre farther back. He improved, but did not get quite well. Then a spontaneous discharge appeared, which disappeared in six months under injections. Then other discharges appeared spontaneously, and finally one testicle swelled. Then another discharge, and his surgeon wanted to cut him again—he had already been cut to 39.

In this condition, with a moderate discharge coming partly from the anterior, but in great part from the deep urethra, the patient applied to me. During five weeks he took a mild anterior injection himself, and I injected the deep urethra six times, the strength of injection varying from one to ten grains in the ounce. This cured him—so that he was better than he had been for several years. This spring he had a moderate relapse, which again promptly yielded to the deep urethral employment of the nitrate of silver.

Case VI. *Double relapsing epididymitis due to deep urethral inflammation.*—A married man, aged thirty-one, came to me in July, 1885, with double swollen testicle. He stated that during his youth he had had gonorrhœa most of the time. At the age of twenty-six, under treatment by the endoscope, he got well and married. A year later first one, then the other, testicle swelled, and he had had shreds of pus in the urine and occasional urethral discharge and trouble in the testicles most of the time since. When I examined him both testicles had been swollen for some time; the right was getting better, the left worse; he had a gleety discharge and much pus in the urine; bladder symptoms were moderate.

I injected the deep urethra, as in the foregoing cases, at a strength varying from one and a half to ten grains in the ounce. Both testicles improved promptly and were well, so far as active symptoms were concerned, in less than two weeks. In five weeks the discharge was cured, and the bladder symptoms overcome. The patient remained well for eighteen months, when he returned for a commencing mild urethritis, said to be due to leucorrhœa in his wife. The testicles were well and had remained so since the deep urethral injections.

Case VII. *Vesical irritability due to enlarged prostate.*—A gentleman, aged fifty-five, came to me in July, 1885, complaining of frequency of urination, every three hours by day in summer, every hour in winter, and of being more or less disturbed at night. The urethra was free from constriction, the prostate double its normal size. During the past his winters have been very distressing, so that, to escape his irritability, he had been obliged to pass the winter in the South. He had been treated by the use of the sound and internal medication without success. I gave this gentleman deep urethral injections of the nitrate of silver, about once a week for three months, varying the strength from one up to nine grains in the ounce. The result was entirely satisfactory. His pain and feeling of fulness in the perineum almost disappeared. He gave up his projected trip to the South in the winter of 1886, and his intervals of urination, even in the cold weather, became prolonged to three and a half hours by day, while he got up only once at night. This condition satisfied him, and during the winter just past I have had no occasion to repeat the injections.

Case VIII. *Oxaluria, with prostatic neurosis.*—A married gentleman, aged thirty-one, suffering from premature ejaculation, imperfect erections, and fulness, throbbing, with dull pain in the perineal region and over the pubis, applied to me in November, 1885. His urine was heavy, 1.030, and full of crystals of oxalate of lime. His general health was good, but his local sensations seemed to incapacitate him for work. His urine contained a few shreds of pus from the urethra. I ordered his medical attendant to use the deep urethral injections of nitrate of silver. Only one was administered. It was probably badly done, for it set up mild urethritis, and the patient declined to make further trial of the method. He became gloomy and despondent, and went for several months to a sanatorium for rest. This relieved his mind, but did not cure his local sensations.

I then personally instituted a course of deep urethral injections in March, 1886, and carried them out by the aid of Dr. Alexander, my then assistant. Improvement commenced at once, and has persisted, so that at present the patient is practically well, fully able to attend to business, and almost free from his local sensations and sexual defects. He still comes up for an injection about once a month, but his intervals are getting longer, and he proposes to live in the country this summer and give up all local treatment.

I might multiply cases showing the value of this means of treatment, but I think the foregoing will suffice to justify the claim I make for a more extended general application of this method in cases of inflammatory and irritative disturbances of the deep urethra and prostatic region, including the neck of the bladder.

In cases of nocturnal pollution the influence is sometimes markedly advantageous, sometimes it fails. In these cases I often make the injections stronger, and once carried the strength up to sixty grains to the ounce, before a satisfactory result was reached. In nervous impotence and lack of erectile power the effect is often

strikingly good. In spermatorrhœa benefit is obtained, but rarely a cure, although I have occasionally in mild cases seen the spermatozoa cease to appear under a course of injections.

I must add, finally, and emphasize the fact to which I have already called attention, that although the range of applicability of the injective treatment is very wide, it is not appropriate for all cases. In some instances it fails totally, but these exceptions are a minority of all cases treated.

1 Park Avenue.

THE TREATMENT OF EMPYEMA IN CHILDREN, WITH PARTICULAR REFERENCE TO THE RELATIVE ADVANTAGES OF ASPIRATION AND INCISION.[1]

By L. EMMETT HOLT, A.M., M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

The subject of empyema is a large one, and one of great importance, especially in children, since more than half of all the cases occur during the first ten years of life. Alongside of the greater liability of young children to this form of pleurisy we have, fortunately, another fact—viz., that the prognosis is much better at this time than later in life. This is so well established that I need scarcely more than allude to it here. It depends chiefly upon the difference in the etiology of the disease at the different ages. Thus, of 110 cases in children, collected by Simmonds, empyema followed pneumonia, the fevers, traumatism, or was idiopathic in 94 cases, while in 12 only was it associated with tuberculosis. This is in striking contrast with the well-known frequent association of empyema and tuberculosis in adult life.

It will be manifestly unfair, then, to contrast results in children with those obtained in adults.

An empyema untreated may result in recovery (1) by spontaneous absorption of the effusion, (2) by evacuation through a bronchus, or (3) by opening externally through the intercostal muscles.

That spontaneous absorption of a purulent effusion in the pleura may occur is beyond dispute; it is equally certain, however, that it is one of the rarest of terminations. I have found reported but two undoubted cases—one by Dr. G. M. Edebohls, of this city, and one by Dr. Eustace Smith. The former case was one of localized empyema; the latter was general. In both the diagnosis was confirmed by exploratory puncture. Three other cases—one by Dr. J. E. Winters, and two by Goodhart—cannot be positively accepted, inasmuch as they lack the demonstrion of the hypoderatmic needle, which alone can be regarded as settling such a doubtful point, although in Goodhart's cases the occurrence subsequently of considerable retraction of the affected side makes the probability a very strong one.

Evacuation through a bronchus and external opening were regarded by the older writers as the best that could be hoped for. With the former I have had no personal experience, and have found it extremely difficult to gather from the literature of the subject enough facts for any generalizations regarding the frequency and termination of these cases. Leichtenstern has met with six cases, with four recoveries. Wilks saw in a single year five deaths from this form of opening, although the age of the patients is not given. It is the almost unanimous opinion that pneumothorax is rarely produced by it in children, on account of the greater elasticity of the chest-walls.

To what extent may we rely upon nature to cure empyema?

Rilliet and Barthez mention 33 cases which received no surgical treatment, of which 4 recovered, 21 died, and 8 were lost sight of. Goodhart reports 8 cases, with 4 deaths. These are rather striking facts, but not more so than the following quotation from Condie's "Diseases of Children," published in 1844:

"When effusion of pus has taken place in the pleura, the case is generally hopeless; nevertheless," he adds, "we are assured that even in a child only seven years of age pus has been evacuated by an operation, and entire recovery has ensued, except some contraction of the affected side."

It is evident that the chances of recovery by nature's unaided efforts are not great.

Before going on to discuss the surgical treatment, let us consider for a moment what empyema is. Essentially, it is nothing but an abscess, the peculiarity being that the outer wall, with which we have to deal, is rigid, and the inner wall is yielding. One of the conditions of cure in every abscess is that the two walls of the cavity come into contact. This is accomplished in the chest by the expansion of the lung. The more completely and the more rapidly expansion takes place, the more certain will be the recovery and the shorter the period required. The chief obstacle to re-expansion is the organization of the lymph covering the pulmonary pleura, which binds down the lung. Every day of delay in removing the pus increases the firmness of these adhesions, and consequently the difficulty of expanding the lung fully, and prolongs the period of discharge. In addition to this condition of the pleura, we have the danger of the development of tuberculosis in the lung itself, and, further, the deleterious effects upon the system of the retention of pus in the chest.

We are now prepared to lay down the indications for treatment—viz., *to get rid of the pus, by the easiest, safest, and most thorough means, as early as possible.*

The only means we shall discuss are aspiration and incision with drainage. Puncture with a trocar, and siphon drainage through a cannula, seems to be really only an incomplete operation of incision. It cannot well be carried out in children, as it is difficult to keep the patients sufficiently quiet to secure perfect success, and as the cannula is apt to become plugged with lymph, which the exudation in children usually contains in abundance.

The advantages claimed for aspiration are as follows:

1. Its simplicity.

2. Freedom from danger. With ordinary skill and clean needles the dangers from aspiration are almost nil.

3. It does not remove the fluid rapidly, and hence allows a gradual expansion of the compressed lung. While in the case of serous effusions collapse has been known to follow the rapid evacuation of the fluid, there does not seem to be the same danger in the case of pus, so that this cannot be regarded as a point of great weight.

4. It does not require general anæsthesia. In view of the dangers of anæsthetics in these operations, this is of some importance.

5. It does not require confinement to bed. In the intervals of aspiration the child may be allowed to be up and about, if the case is not an acute one, and thus get the advantage of fresh air. This possible advantage, unfortunately, is more than counterbalanced by the danger of converting the pleural cavity into a chronic abscess-sac, by frequent tapping and prolonging the case indefinitely.

6. That many cases are cured by aspiration alone; the fluid after one or two aspirations becoming serous, it then being readily absorbed.

The advantages, except the last mentioned, are not sufficient to demonstrate the superiority of aspiration to incision. It remains, then, to discover in what proportion of cases, and in what particular variety of cases, we may expect aspiration to cure empyema.

Of 121 cases so treated, collected from various sources, mostly English and American, 23, or nineteen per cent., were cured, 6 died, and the rest came to some other method of treatment, usually incision. Of the 23 cases,

[1] Read before the New York Academy of Medicine, May 19, 1887.

8 were cured by a single aspiration. The variety of the disease was noted in 13 cured cases, and in all but one the empyema was localized.

It is only just that the statistics of Branthomme should be mentioned. I have not had access to his thesis, but his cases are quoted by Moizard. Of 43 cases treated by aspiration, 18 were cured by a single operation, 11 cases by two operations, 3 cases by three, and 11 by a variable number, ranging from six to one hundred and twenty-two. The last case extended over a period of eleven months. These French statistics are quite at variance with the results published by German, English, and American writers. I present them without comment.

Aspiration has some very obvious objections :

1. By it not all the pus can be removed ; there is always a residue to be gotten rid of by absorption.

2. When the exudation is divided by septa, we may empty one sac, but leave another untouched ; while after a free incision the finger or a catheter may be introduced and all these septa broken down.

3. The terror of the child at the operation, in cases where it becomes a necessity to repeat it, is a very serious objection, the full force of which one can only appreciate who has had to contend with it.

4. There are certain cases to which, from their nature, aspiration is not applicable ; as when the pus has become septic, when empyema is associated with gangrene of the lung, or when the exudate contains much fibrin, clots, or shreds of necrotic pleura.

5. It offers, after all, only the *possibility* of cure ; by persisting in it valuable time is consumed, by which the success of incision is jeopardized, and the time of treatment prolonged, so that the patient is exposed to the dangers of septicæmia, exhaustion from long-continued suppuration, and imperfect expansion of the lung.

Incision possesses the following very decided advantages over the method we have been discussing : Its universal applicability ; the fact that it enables the surgeon to explore the cavity with the finger, breaking down adhesions or septa which may prevent perfect evacuation, to remove clots and shreds of necrotic tissue, to wash out the pleura in case it may be necessary from the septic character of the pus, and to drain completely.

The admission of air into the chest and septic absorption from the wound have been regarded as the chief dangers in empyema operations. Since the thorough use of antiseptics in these cases, these objections can no longer be said to have any weight. A comparison of the results given below of simple and antiseptic incision is a conclusive argument upon this point.

The use of general anæsthetics remains to be considered. I have twice known rupture into a bronchus to take place while the patient was unconscious, and death to result from suffocation. These cases were both in adults. I have not found upon record such an instance among children ; but it might easily occur in a case of long standing. The conclusion to be drawn is, that in such cases, at least, local anæsthesia should be relied upon, perhaps in all. I am not aware that cocaine has been applied to this operation, but it would seem that with it we might be able to dispense with general anæsthesia altogether. With it I am sure no more pain and fright would be produced in a child than by aspirations.

Considering the results they obtained, it is not strange that the older surgeons should have held this operation in very low esteem. Thus Astley Cooper held that it was always fatal. Dupuytren operated in 50 cases, with only 4 recoveries ; and when himself suffering from empyema, refused to have it performed, saying that he "preferred to die by the hand of God than the hand of man." Diffenbach had better success ; he operated in 46 cases, two-thirds of which recovered. In the above statistics the ages of the patients are not given, so that it is impossible to say what were their results in children.

Coming down to more recent times, 59 operations in children, with 8 deaths, have been collected by Blume and Simmonds, in most of which antiseptics were used to some extent. While of the latest reported cases treated with full antiseptics, I have collected records of 63 operations, with 2 deaths. Of this number, 26 successive cases were treated by Goodhart and Taylor in the Evelina Hospital, London, with one death, that being from complicating pericarditis and peritonitis.

Could anything be a more complete demonstration of the merits of this mode of treatment ?

A case mentioned by Gwynne illustrates so well the necessity of complete antisepsis that we may be pardoned for introducing it.

A child five years of age was operated on for an empyema of the right side, and the wound dressed antiseptically. On the sixth day the patient pulled the dressings off, and the wound was exposed to the air for some time. On the next day the temperature rose from 98.6° to 105° ; the discharge, which had been free from odor, became fetid and death occurred in a week.

I have collected 80 cases treated by antiseptic incision, in which the *duration of the discharge* was given. In 5 cases it was four months or over ; these being, for the most part, cases of long standing at the time of operation. Of the remaining 75 cases the average duration of the discharge was six weeks. In 21 of these, most of which were operated upon early, the duration was one month or less.

The discharge lasted, in cases where no antiseptics were used, in 5 cases (Hobson) an average of six months ; in 40 cases (Blume), where they were partially used or not at all, three to six months ; in 11 cases (Simmonds) an average of eleven weeks.

The following conclusions may be drawn from this consideration of empyema in children :

1. All methods of treatment yield better results than in adults.

2. We are never justified in leaving a case to nature.

3. Aspiration holds out a reasonable prospect of success in cases of localized empyema ; but a very slender one when the exudation is general.

4. If, after two aspirations at most, the pus reaccumulates and shows no tendency toward a transition to serum, this method should not be persisted in.

5. In cases of a large effusion, one aspiration may be done preliminary to the cutting operation, to avoid any possible danger which might result from a too rapid withdrawal of the fluid.

6. In all other cases a free incision should be made as early as possible, preferably under local anæsthesia, always with the strictest antiseptic precautions.

7. The operation of puncture with a trocar and drainage aims at a cure by the same means as incision ; but it is not more safe and very much less certain.

8. Excision of the ribs is rarely required ; never in early operations, as it appears to prolong the discharge without giving any corresponding advantages.

9. The treatment of empyema cannot better be epitomized than in the words of Wagner : "*Early incision, perfect drainage, and complete antisepsis.*"

Under this method this affection, from being one of the most fatal of childhood, has become one of the most amenable to treatment.

15 East Fifty-fourth Street.

Pruning Shears for Use in Autopsies.—Dr. T. E. Quimby, of Fayetteville, N. Y., writes : "I have been using at autopsies the 'pruning shears No. 52,' to be obtained at hardware stores at a cost of fifty cents. They sever cartilage or ribs with rapidity and ease, being vastly superior, I find, to the cartilage-knife. It is an excellent instrument as regards size, weight, strength, and finish, keeping sharp a long time."

Women are more often hungry than men, says M. Delaunay.

ACUTE EMPYEMA IN CHILDREN.[1]

By FRANCIS HUBER, M.D.,

NEW YORK.

"Of all chest diseases in children, mistakes in diagnosis are most frequently made with pleuritis." This is particularly true of cases which, from the outset, are attended by the secretion of pus, and which have been termed acute suppurative or purulent pleurisies—acute empyema. Acute empyema is not at first a simple, and later on a suppurative, process; it must be regarded as a distinct variety, the inflammation of the pleura being severe in type and accompanied by the secretion of pus from the very beginning. Such cases are met with principally in the thickly populated districts under poor hygienic conditions. Some of the patients are, or have been, rachitical. Others may apparently be in fair health, running about as usual, and without any history of exposure or other assignable cause be taken down in a few hours with chill, nausea, or vomiting, or convulsion. The onset is sudden. The fever is high from the commencement, and varies from 103°, 104°, 105°, or over. There is marked prostration with severe constitutional disturbance. The children are restless, crying continuously.

The cough, suppressed at first, is more or less severe later on. Respiration is short and catching in the beginning; soon dyspnœa becomes more and more pronounced. Emaciation is rapid. The fever may continue for six, eight, or ten days, and then subside. The other symptoms gradually improve to a certain extent, but the little patient continues weak, pale, emaciated, and troubled with occasional diarrhœa, until the disorder is correctly diagnosed and the proper treatment instituted. The fall in the temperature is a favorable sign. In other cases the fever persists, the vital forces are seriously involved, there is rapid failure, and the case terminates fatally within ten days to two weeks. These children die from the intensity of the suppurative inflammation. The effusion, as shown by the physical signs, appears at a very early stage, and increases very rapidly. In a child eighteen months of age, the physical signs showed considerable fluid on the third day; on the fourth day a hypodermic syringe was introduced and its purulent nature established; the next day about twelve ounces of pus were removed by aspiration. In a boy eleven years of age, seen in consultation with Dr. Neufield, I removed a pint and a half on the fifth day. In another child aged eleven months about twelve ounces were taken away on the ninth day.

In some instances—I have three such in my own practice—the purulent process may be coincident with an acute pneumonia, the two going on at the same time, and it is impossible to say which occurred first.

A fourth I saw quite recently, in consultation with Dr. J. Horn, and about six ounces of pus were drawn off on the fourth day.

In another case, which I saw with Dr. Denhard, there was, at the same time, a pneumonia of the right side and an extensive purulent effusion on the left. We were obliged to postpone active interference in this case, on account of the collapsed condition, until the eleventh day.

A careful physical examination of the chest, with the early use of the hypodermic syringe, will enable one to arrive at an early diagnosis in the complicated cases.

The primary acute empyemas in children are more serious than those running a subacute course, and a guarded prognosis should be given during the first fortnight. A number prove fatal before the end of the second week. Thus I have seen four cases which terminated fatally as follows: First, aged nine months, died on the tenth day; second, aged eleven months, died on the eleventh day, two days after aspiration; third, eleven years of age, died on the eighth day, with a pericardial complication; fourth, aged eighteen months, died on the sixth day, fifteen hours after aspiration.

[1] Read before the New York Academy of Medicine, May 19, 1887.

Barthez and Sanné report that of twenty-one non-tubercular cases not operated upon, seven died in from eleven to sixteen days.

The physical signs and clinical history do not enable us to arrive at a positive diagnosis of acute empyema. We can determine the presence of fluid in the pleural cavity at an early stage; the character of the fluid, however, remains doubtful. Chills, fever, diarrhœa, and other hectic manifestations are observed in the late cases. Localized œdema on the affected side is frequently absent. The presence of a soft, fluctuating tumor in one of the intercostal spaces in a case of pleural effusion ought to lead one to suspect the purulent nature of the disease. This does not occur until a late period in the disease, though in one instance I saw it appear as early as the nineteenth day. If the quantity of fluid continue to increase in an acute case of pleuritic effusion, in spite of measures intended to promote absorption, pus is probably present. Or if in an acute pleurisy the fever be intense and the constitutional disturbances severe, the inflammatory products are very likely suppurative in character.

An absolute diagnosis, however, can only be made by an exploratory puncture with a hypodermic syringe, a large needle being used. It is a simple and safe procedure, and with ordinary care no harm can result. An early resort to puncture is warranted in view of the importance of a positive diagnosis in its bearing upon the prognosis and treatment of the case. Attention to the points developed above has enabled me to make the diagnosis as early as the fourth, fifth, sixth, seventh, ninth, and eleventh day, of the disease.

The treatment by medicinal means is symptomatic and palliative. No reliance can be placed upon measures intended to produce absorption of the purulent products. Our therapeutic resources enable us to combat special symptoms and improve the general condition with the aid of tonics, good food, and stimulants of various kinds. Whenever possible, the children should be placed under better hygienic surroundings. In the active inflammatory stage the treatment is symptomatic. Caffein, camphor, carbonate of ammonia, and other heart stimulants are particularly indicated.

An expectant plan of treatment is dangerous and ought to be condemned. "One of the large serous cavities, connected as it is with the lungs, is not only disabled, but contains a deleterious fluid which cannot remain in a closed cavity without sooner or later affecting the processes of nutrition." The amount is too large to allow it to become encysted, and nature cannot remove such quantities by absorption. We must get rid of the pus and stop the suppurating process. An empyema can never be cured unless the cavity of the pleura is obliterated by the expansion of the lung, the ascent of the diaphragm, the displacement of viscera, or the falling in of the chest-walls, or all of these together. Surgical measures only enable us to meet these requirements. The more promptly we act, the greater the prospects of cure. Not only must we endeavor to save life, we should at the same time aim to save the lung and secure to the patient the power to expand the lung fully. An early diagnosis and early resort to surgery will aid us materially in this respect.

The presence of pus being established, its removal may be accomplished by aspiration or incision. The question now arises, When shall we interfere in the early cases? Though I am in favor of early puncture in order to arrive at a positive diagnosis, I would defer aspiration until the acute febrile condition has subsided—say until the tenth or twelfth day—provided the presence of the fluid in the early stage does not endanger life in any way. In acting accordingly, I do not forget that some authorities as Castiaux, Wedal and Montard-Martin have practised aspiration in acute pleurisies (serous in character) with advantage at a very early period (second to tenth day). The two conditions are not analogous.

The shock to the system in acute purulent pleurisy is profound, the pulse is weak and feeble from the beginning. Waiting a few days, if the fluid be not excessive, allows the patients to rally and improves their condition and chances. I would not be misunderstood here, for I do not favor temporizing; it is only during the first week or ten days that I would advise a judicious delay, in order to allow the little patient to recover from the collapsed condition.

As a matter of fact, I have, on several occasions, waited for from four to seven days, and have not had occasion to regret the conservatism. On the contrary, the pulse was improved and the general condition better when operative means were employed.

Aspiration may be resorted to in the first instance. My individual preference is to puncture in the sixth or seventh intercostal space, near the posterior axillary line, a hypodermic needle being first employed to establish the presence of pus at the spot selected. As a general thing, an anæsthetic, local or general, is not required. Enough to relieve pressure may be removed, or the attempt may be made to rid the pleura of all the deleterious fluid. Too much ought not to be attempted at one sitting. If the cough becomes annoying we must rest contented with the removal of a small quantity, and further attempt can be made later on. If, after aspiration, the pus is found to be laudable and inodorous, and if it does not refill rapidly, or if the fluid at subsequent punctures becomes less and less purulent, the tappings may be repeated with fair prospects of ultimate success. In acute empyema, according to my experience, it is merely a temporary expedient and does not succeed even when employed early. Within a few days the pus reaccumulates to the same extent, or may even exceed the quantity removed. Under such circumstances more radical measures are indicated, and when I find that the physical signs, a few days later, show as much or a greater amount of fluid, the aspiration is not repeated, but the chest is incised at once. Not only do we have pus in large quantities in these cases, fibrin is thrown out at the same time, too dense and abundant to be removed through the needle. The infrequent cures after this method must, in my mind, be attributed to the presence of fibrinous deposits upon the pleural surfaces and in the the cavity. In several of my cases septic symptoms developed after aspiration, and upon opening the pleura the fibrin was found in a decomposed state. I do not think that the infection was carried in by the needle, for the usual precautions were taken to keep the instrument aseptic. It is probable that the fibrin interspersed with pus is decomposed more readily when the liquid portions are removed. Delafield states that the fluid in the pleural cavity, the fibrin and pus coating the pleura, and the pleura itself may putrefy, with the production of bacteria and the evolution of gases. This may take place either in a closed pleura or in one which has been opened ("Pathol. Anat.," etc., p. 213).

If the patient be cachectic, the hectic fever of a severe type, if perforation have taken place, septicæmia be present, or the fluid return quickly, or contain considerable fibrin, aspiration will fail, and we are then forced to employ the open method.

In acute empyema a simple incision an inch or an inch and a half long, with insertion of drainage-tube and antiseptic irrigation and dressing will answer.

A preliminary explorative puncture is made in the sixth or seventh intercostal space near the posterior axillary line. If pus be not found in this situation another puncture is made posteriorly, about an inch below the angle of the scapula. A grooved exploring needle is now introduced until the pus cavity is reached, and an opening sufficiently large to admit a director is then made with a tenotomy knife, so as to permit the pus to escape slowly. Finally, a probe-pointed curved bistoury is introduced and the opening enlarged to an inch or an inch and a half. The edges are then held apart by means of dressing-forceps or Trousseau's tracheal dilator to permit the escape of large fibrinous masses. The drainage-tube is then introduced and the cavity washed out with an antiseptic solution, and an antiseptic dressing is now applied. In order not to wound the diaphragm, the cutting instruments are introduced but a short distance and the intercostal artery is avoided by keeping close to the upper border of the rib. General anæsthesia is not required in these cases—cocaine injected locally will suffice.

I have resorted to this plan in thirteen itstances; of this number three died—one of exhaustion, one of acute gastro-intestinal catarrh, and in the third case erysipelas set in. Of the remaining cases, one is still under treatment was one is left with a sinus secreting a few drops of pus daily, and the others have recovered with power to expand lungs freely. The youngest was aged nine months, oldest five years. The average period of treatment about seven weeks.[1] The most rapid recovery occurred in a child patient of Dr. Neufield, aged twenty-one months (rachitical and the weaker of twins). In this case the chest was incised on the fourteenth day of disease. Under injections of bichloride, and bichloride gauze and borated cotton dressing, the cavity (originally holding about one pint) was obliterated and the external wound closed within three weeks.

Injections have been employed in all cases, for fibrin is present in large quantities and decomposes very readily unless removed by irrigation. Solutions of bichloride of mercury, 1–5,000, the final flushing being of the strength of 1–10,000, allowed to flow in gently, answer the purpose and give excellent results. The cavity contracts quite rapidly, and after three to six weeks does not secrete more than a drachm daily. Several weeks more elapse before it is wholly obliterated and the sinus healed. The drainage-tube should not be removed too early, we ought to wait until a mere sinus is left.

A word as regards the rubber drainage-tube. A good tube is recognized by the following characteristics: 1, Transverse markings in the rubber; 2, lightness—should float on water; 3, it should bear being tripled in length without breaking. To prevent it slipping into the pleural cavity I have adopted the plan suggested by Baxter, of Kings' College Hospital. A round hole is cut in a piece of rubber sheeting about one-twelfth inch in thickness and an inch and a half to two inches square. A tube of the size required is then split at one end into two pieces and drawn through the aperture in the flat piece of rubber, turned down, and fixed in position by stitches of silver wire. The tube should be just long enough to project into the chest cavity—one and a half to two inches. Nothing is gained by curling up an enormous length of tubing in the chest. The retraction of the chest on the affected side is temporary and disappears in a month or six weeks, under proper gymnastics and outdoor exercise.

In concluding, though I may not present anything new, I would lay stress upon and call particular attention to a few points frequently overlooked in acute pleurisies in children.

1. In acute pleuritic effusions pus is probably present in a case in which the constitutional disturbances are severe and the fever is high at the outset.

2. If the effusion does not diminish, but continues to increase under treatment, it is probably purulent.

Under the above circumstances an early explorative puncture is indicated.

3. If aspiration reveals a purulent fluid containing numerous flocculi of fibrin, or if (after aspiration) the pus returns quickly to the same extent or is increased in amount, aspiration is of no avail and more radical means must be employed. Finally, if septic symptoms are present, in cise at once.

[1] Chest incised as follows: Case 1 on the twentieth day: Case 2 on the twentieth day; Case 3 on the twenty-first day: Case 4 on the twentieth day; Case 5 on the fourteenth day: Case 6 on the twentieth day: Case 7 on the twentieth day; Case 8 on the twenty-fourth day; Case 9 on the fifteenth day: Case 10 on the sixteenth day.

THE SURGICAL MANAGEMENT OF EMPYEMA.[1]

By ROBERT ABBE, M.D.,

ATTENDING SURGEON ST. LUKE'S HOSPITAL, NEW YORK.

In considering the surgical handling of cases of empyema, as Dr. Hudson, our late lamented chairman, desired I should do, very briefly, I would say in beginning that the first thought that should come to the mind of the physician in the presence of such a purulent collection, should be, "Abandon all thought of promoting absorption of the pus and rid the patient of it by the quickest and safest means."

No fixed and settled rule of procedure can be formulated for the management of all cases. Each has a character that determines which is the best method of relief. The practitioner of limited experience finds himself confronted by a choice between methods, each of which has advocates. He asks himself shall I do simple aspiration, or thoracentesis by trocar and cannula, or aspirate and irrigate through the needle, or shall I simply incise and evacuate, or incise and insert drainage-tubes, and if so, shall I work with or without antiseptics; and shall I drain the pus into a dressing or put the end of my tube under water (the so-called "subaqueous" method), or shall I have "through drainage" with two openings, and, if so, with or without antiseptic or aseptic irrigation. If I incise, he may further ask, shall I resect one rib, or remove a piece from several ribs (thoracoplasty), or lastly, shall I adopt "perflation?"

A brief review of these proceedings will promote an intelligent understanding that will lead to the wisest decision for each case.

Every surgeon of experience admits that aspiration repeated several times is competent to cure a small number of cases of empyema. They are of the simplest type and would do well by any method of treatment, except the expectant. It is specially adapted to cases before puberty and the aspiration may be often repeated. A few well-authenticated cases have been cured by one aspiration. Yet to the surgical mind there is always regret at leaving ever so little pus that will ultimately make an inspissated residuum, which in adults has been known to make secondary abscesses years after. If, after the aspiration of all that can be removed, the pulse and temperature rise, chills follow and the patient is no better no time should be lost in freely opening the pleura. It was long ago proposed to irrigate the cavity through the aspirator needle with antiseptic solutions, but there is no literature to show that the results are good, and the method does not appeal strongly to practical operators.

Thoracentesis by trocar and cannula is the oldest and one of the best methods of evacuation, though second to the aspirator on account of the possibility of air being sucked in. If this does not happen it is conceivable that adhesive union of costal and visceral pleura may take place after the complete emptying of the cavity. A few older operators advise a simple incision and letting the pus flow, but it is only after months of tedious suppuration that healing is thus accomplished and then after untold labor in keeping open the wound, with the incidental risk of blood-poisoning.

By far the best results yet attained, however, are known to follow, in most cases, free incision followed by the insertion of drainage-tubes. Some have advocated the opening made as low as the ninth or tenth interspace, so as to drain from the lowest point of the cavity, others at the fifth space somewhat forward of the axilla, because this seems most often nature's point of election in spontaneous opening. Accumulated experience now shows, however, that the seventh or eighth intercostal space is best, for the reason that, in the natural process of closure, all the boundaries of the contracting cavity approach that point. Just in front of the posterior axillary fold, on the line of the eighth space, a free incision two inches or more in length, parallel to and above the upper border of the rib, should be made by a couple of bold strokes of the scalpel. As the pus flows freely, being at first under some intrathoracic tension, no time should be lost in inserting two large drainage-tubes the size of one's little finger, not more than two inches long. They are transfixed at the skin level by a safety pin, just outside which they are cut off. Each inspiration tends to draw in air as the fluid level falls, and we must be prepared with a spray, for which I have found sufficient a hand-bulb atomizer, using carbolic acid (three per cent.). As soon as the flow ceases on inspiration, the tubes must be covered either temporarily by a cloth wrung out of carbolic water or by the sublimate gauze dusted freely with iodoform. Thus what air gets in is practically pure. Is it necessary that the cavity fill up with air? No! for we might conduct the pus to a bottle half full of carbolic water into which the end of the tube is thrust and thus effect subaqueous drainage. This seems simple and rational, but in practice this drainage is inefficient.

What we want *first and last* is a *thoroughly free outlet.* One operator says he succeeds best because he stuffs his wound full of drainage-tubes. I thoroughly believe that the size of the wound and completeness of the evacuation will determine the speed of convalescence. The purity of the wound is the other important factor, and is gained, first, by the carbolic spray, and, second, by dressings. Undoubtedly there are atmospheres like our Colorado and mountain air which are for practical purposes aseptic and the spray may be discarded, but in cities and hospitals I have no doubt the course of suppuration is very greatly abbreviated by Listerism.

There is no need of irrigation of the cavity in the great majority of cases. Those only where the pus is putrid at the initiative and offensive when evacuated, or where, from neglect of the precautions mentioned, the cavity has become septic and the patient has pronounced hectic, need to be irrigated, with antiseptics first and hot water afterward. Bichloride of mercury solution (1 to 3,000) is best, or very weak carbolic or iodine water—made with tincture of iodine until the solution is the color of sherry.

The two risks of irrigation are the toxic action of the solutions and the sudden death that has occasionally been known to occur in cases undergoing washing out of healing cavities. The latter accident has happened equally often when carbolic or iodine solution or pure water was used. Post-mortems have not revealed the cause of these fatalities and the suppositions left to explain the event are that either thromboses or reflexes from the pleura have caused fatal syncope.

Toxic action after irrigation only seems to happen when the drainage is not perfect and some fluid is left for absorption. The result of using "through drainage," so called, is to leave the cavity drier perhaps than by other means and thereby to insure a greater immunity from absorption.

Through drainage is accomplished by inserting a metal sound into the cavity through the first opening and pressing its point outward at the lowest intercostal space, cutting a counter opening there, through which a drainage-tube is drawn and brought out above.

While this does drain well for a short while, it is soon shut in by the natural reparative action which usually seals the diaphragmatic and costal pleura together in this region as one of the earliest of nature's steps toward repair.

How these processes bring about the ultimate union of the lung to chest-wall, in direct antagonism of the collapsing, retracting power of the lung-tissue, is quite a puzzling question. Mr. Godlee thinks, if I understand his idea aright, that, in view of the occasional discovery of areas of adhesions in advance of the border of the sac, the lung thus creeps up by grasping ahead, as it were, and then the sac draws close behind that point.

[1] Read before the New York Academy of Medicine, May 19, 1887.

It seems to me the general contractility of this plastic lymph-sac drawing on the yielding lung-tissue is a sufficient force to bring about the closure of the pleural cavity, adhesion between lung and wall following close behind the contracting angles of the sac. Thus the diaphragm is lifted, the mediastinum drawn to the affected side, and so on, as contraction progresses.

The presence of drainage-tubes between ribs usually causes the bone to be denuded of periosteum at the point of contact. This is wrongly spoken of as necrosis of the rib, and some eminent surgeons advocate the removal of a section of one rib, an inch and a half long, at the first thoracentesis, thus anticipating what is frequently needed later. It is certainly, I think, unjustifiable at the first, and the patient can usually bear it better later.

The question of the use of anæsthesia confronts the operator anew in each case.

For children a few whiffs of chloroform are sufficient to allow incision and adjustment of tubes, and is always desirable—for they usually bleed rather freely from their highly vascular skins, and one is annoyed by their unmanageable struggles.

In adults the local anæsthesia of ether spray, rhigolene, or freezing by ice and salt, are quite satisfactory, but a superior method is by cocaine anæsthesia. Twelve drops of a four per cent. solution are amply sufficient if placed rightly. One-third of this may go into the intercostal muscles, and the rest under the skin or in its substance on the posterior edge of the area to be invaded, for one sees here that the numbness extends from behind forward along the peripheral distribution of the nerve filaments bathed by the cocaine. It is folly to attempt to cut until complete local anæsthesia, which occurs in from ten to fifteen minutes after injection. I have no doubt one might resect a piece of rib without other anæsthetic and without pain, though I have not done it.

The resection of a rib is needed where it is necessary to clear the cavity of a quantity of decomposing fibrin exudation that often lies detached in large, ragged masses, blocking the exit if it is not large. This may be freely torn from its site, if not loose, without fear. Such cavities usually need irrigation with one per cent. carbolic acid or boiled water.

The patient requires ether anæsthesia for resection. The instruments needed are very few. I have usually found a scalpel, after a longitudiual incision has been made down to the bone, furnishes in its handle the best periosteum elevator. This peels off readily, and the handle insinuated under the rib raises it for the action of a rongeur, with which the rib can be gnawed through at two places as quick, if not quicker than it can be sawn, and the instrument is at hand to round off the ends of bone. An inch and a half of rib should be removed. It is better to take too much than too little. The scalpel may incise the pleura just where the rib was, and then cut upward to the next rib, avoiding thus the intercostal arteries. But these, after all, are not to be dreaded, as popularly supposed, for their hemorrhage usually stops spontaneously without ligature. One should have forci-pressure forceps, however, in case of need.

There is usually but little difference in breathing, so far as the patient is aware, for the air entering the cavity only replaces pus that had compressed the lung against the vertebra.

Drain-tubes should be shortened, but retained until the discharge has nearly ceased. In children they may come out in two or three weeks. In adults twice as long.

If, after the tubes are out, the hectic returns, the wounds must be reopened and free vent given to the discharges.

This simple aid to nature in giving free drainage is not successful in curing every case. There are seen from time to time advanced cases that have resisted all ordinary attempts at closure by stimulation, drainage, and irrigation; the cavity walls are indurated and secreting poor pus, the chest has heavy, resisting ribs, or there may, perhaps, be phthisis combined with empyema, where many months, or even years, have passed since tapping. The cavity has usually become reduced to the size of one's fist, and cannot spontaneously close farther. They may easily pass for old phthisical cases, as readily as an acute empyema, when discharging into a bronchial tube, with its hectic, emaciation, and expectoration, may resemble an acute phthisis case.

To meet such cases a simple plan was devised by Estlander, and put in operation in 1877, though not published until 1879, in the *Revue mensuelle de Med. et de Chirurgie*, pp. 157–159. He argued that to resect from one to three inches of half a dozen neigboring ribs in the axillary line would allow the ribs to approximate and the cavity to collapse, and thus be put in a condition for repair. He held that the operation ("thoracoplasty") should not be done under six or eight months after primary evacuation of the pleura, and showed that it may be resorted to at very late dates in cases emaciated to a skeleton, and so weak as only to be able to walk a few steps. Carefully done, it causes but slight disturbance to the system, and almost incredibly rapid improvement follows.

The method of removal of portions of several ribs varies from that for one only in that the incision may be made vertically in the axillary line, crossing all; or, several cuts parallel to the ribs may be made, each lying between two ribs, and through it both can be reached. Enough of each rib must be removed to correspond with the depth of the cavity from the rib to the lung—those on the edge of the cavity requiring, perhaps, an inch, while the centre one may require three.

The bones may be removed without opening the pleural cavity, the approximation of the cut ends allowing the outer wall to fall inward. It is, however, often advantageous to cleanse an old cavity, and even, in some cases, to pack it with iodoform gauze and encourage granulation.

The plan of relief is so rational that it appeals to surgical minds everywhere as the most available method for relieving the occasional cases where a suppurating cavity remains after empyema, and the results have not been disappointing to those who have resorted to it. It is rather evident, though, from published cases, that it has been tried in some patients before the natural course of healing through a single drain had come to a stop.

Finally, a method of forced evacuation of the pus from the chest was last year devised by Mr. William Ewart (*Lancet*, July 31, 1886), who proposed forcing carbolized air into the pleura, and causing the pus to be emptied through a drain carried to the bottom of the sac. The stream of air thus also ventilates the sac in every corner and keeps it sweet. It could be used with force enough to expel shreds of membrane that would otherwise plug the tube of exit. The method he calls "perflation," but offers no proof of its benefit except on theoretical grounds.

It may fairly be said that it will never supplant free drainage, because it cannot be more aseptic, more thorough, or more simple than this, if rightly applied.

Unhesitatingly, then, I would say that the quickest and safest relief from acute empyema is in the early and liberal incision, with large drainage-tubes and strict antisepsis; while for very chronic cases the method of Estlander offers great hope of relief.

Clinical Department.

A CLEAN DOUBLE-BARRELLED CATHETER.

Dr. H. N. Allen, of Seoul, Corea, writes: "Such an instrument may be readily improvised for washing out the bladder (especially of a female), by making an eyelet on the opposite side of a No. 12 rubber catheter, and passing into the No. 12 one of say No. 4 size. The fluid can then be injected through the No. 4, coming out through the regular eyelet of No. 12, and returning through the newly made eyelet. As this idea occurred originally with myself, I presume it has already occurred to many other practitioners. But as it may not have suggested itself to every one to whom it may be useful, I mention it for what it is worth. It allows of the employment of a new, clean instrument for every case, as well as supplies the demand when the regularly made article is not at hand."

A CASE OF CHOREA GRAVIDARUM.

Dr. G. W. H. Kemper, of Muncie, Ind., reports the following case: "Mrs. E. F——, aged twenty-three, became pregnant the second time in March, 1882. She had usually enjoyed good health except in the fall and winter of 1880, when she suffered from an attack of inflammatory rheumatism. On July 21, 1882, while residing near Alexandria, Ind., she was seized with some acute illness which was diagnosed by the medical attendant as "brain fever." On the morning of the 27th, while confined to her bed with this attack, the house in which she lay was burned, and she received a great fright. The next day after this event choreic symptoms appeared, and the characteristic phenomena gradually became more marked. On August 12th her condition being temporarily improved, she was brought to her parents' home in Muncie. After her arrival she was under the professional care of Dr. E. J. Puckett. I was requested by that gentleman to visit his patient in consultation, and did so on August 31st. Her condition at that time was most pitiable. She was utterly unable to perform any voluntary movement. The bedstead was covered with cushions to guard her from injury, and she was incessantly tossing from side to side, while the extremities were constantly exercised in irregular spasmodic efforts. The facial muscles alternately contracted and relaxed. She was unable to articulate with any distinctness, and deglutition was so imperfectly performed that she was badly nourished. Her tongue had been repeatedly bitten and was swollen. The expression of her face was decidedly idiotic. I was told that this condition had existed for a number of days previously. Large doses of opium had been given without relief. We gave chloral in half drachm doses, with only temporary and partial relief. In short, inhalations of chloroform alone gave rest and ease. Her temperature was 104° on the day of her death, which occurred September 2, 1882. No attempt was made at labor, and owing to her weakened condition, I did not deem the induction of labor proper at the time I saw her."

INTUBATION OF THE LARYNX IN A NEGRO —RECOVERY.

Dr. Frank Tipton, of Selma, Ala., reports the following case of intubation of the larynx, which he claims is the first performed in that State: "I was called, on March 28th, to see a negro child on my plantation, adjoining this city. I found on my arrival a well-marked case of obstructive laryngitis, with all the symptoms of imminent suffocation. The child was four years of age, of unusual intelligence, but of feeble physique and stunted development. No false membrane could be detected in the faucial tract, on the tonsils, or in the pharynx. Having been called hurriedly from my office, I had no laryngeal mirror, and could make no examination of the air-passages. Even depression of the tongue caused such violent suffocative paroxysms that I was obliged to desist. I was unable to see the child again until the following morning. Some time before, my partner, Dr. Furniss, had insisted on adding to our stock of instruments a set of O'Dwyer's tubes. These I took with me, thinking to try them first, and if this failed to resort to tracheotomy. I found the child so nearly dead that I could not stop to make a critical examination with the laryngoscope, but proceeded at once to intube the larynx. The child was then cold, pulseless, covered with a profuse clammy sweat, and deeply cyanosed in those parts which are normally pink in the pure negro. The breathing was distressing, and was so stridulous and rasping that it could be heard even before we entered the cabin. I at once directed a strong negro to wrap the child in a blanket and hold him in O'Dwyer's position, while my student, Mr. Coleman, held the head and watched the gag, and I proceeded to make my first attempt at intubation. The writers all say, 'Do not attempt it without some preliminary practice,' but I felt assured that I could do it. After about five unsuccessful trials I slipped the tube into its place, and the bad breathing stopped as if by magic. I turned away to clean the introductor, and hearing the boy say 'I want to pit,' told the grandfather to wipe away the saliva with a towel. The old man, in his excitement, caught the silken cord which I had not yet cut, the tube was dragged out of the larynx, and was swallowed before the cord could be grasped. I was so upset that I did not know what to do, but the child soon became so bad that a second tube had to be inserted. This time I succeeded beautifully, and have never had any trouble since. The child took food well, the pulse returned, the body became warm, and from his moribund condition the boy returned to a state of comparative comfort. I cannot refrain from relating an incident exemplifying the faith that the negro has in the Supreme Being. As I was telling the mother that the chances of recovery were pretty slender, the little fellow looked up with an expression of perfect faith and said, 'O Lord, Thy will be done.' The child did well from the time that the second tube was inserted. On the sixth day after the intubation I removed the tube, but was soon obliged to reinsert it. The swallowed tube was passed from the rectum on the tenth day without having caused any trouble. I learned that the key to the successful insertion of the tube is to put the index finger well on the upper surface of the vocal cords. If this is done it is very easy to slip the tube over the pulp of the finger to the glottis; the point of the tube should then be pressed well against the anterior surface of the vestibule of the larynx by elevating the introductor, when it slips easily into the chink of the glottis. I also learned that the physician should never leave his patient without first putting the index finger well down to the head of the tube to see if it is in proper position. Failure to do this nearly caused the loss of my patient, who coughed up the tube one day, in consequence of my neglect to take this precaution. On the suggestion of the patient, I succeeded in feeding him without much trouble by using a nursing-bottle for his milk and other fluids. The great trouble in feeding these cases generally comes from the difficulty in swallowing fluids, some of which will go the wrong way despite all our precautions. This is caused by the failure of the epiglottis to completely close the opening in the tube, and is best prevented by the nursing-bottle, which obliges the patient to swallow slowly. The points of interest in this case are, that it is the first recorded case of intubation in a negro, the first in this State, and the first in which the tube was swallowed and passed per anum. The suggestion of feeding with a bottle is also, I think, of value."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 28, 1887.

THE ANTISEPTIC ACTION OF IODOFORM.

IT seems rather odd that anyone should, at this day and in the face of clinical experience, deny the antiseptic action of iodoform. Yet not long ago Drs. Heyn and Rovsing, of Copenhagen, published in the *Fortschritte der Medicin*, a report of some experiments undertaken by them, the results of which seemed to prove that this substance was inert in the presence of bacteria, and they therefore concluded, on purely theoretical grounds, that iodoform should not be used as an antiseptic in surgical dressings. This might have been sufficient to condemn the drug at the time when it was first introduced into practice, but at the present day surgeons would hardly be influenced by any theory which years of practical experience had taught them must be fallacious. However, the experiments were there, and it remained to explain them away.

At the meeting of the German Surgical Congress, held in Berlin in April of this year, Dr. de Ruyter read a paper in which he showed that, while the experiments were correct as far as they went, the conclusions drawn from them were erroneous. He found that, as the Danish physicians had asserted, iodoform in the form of a dry powder, outside of the body, exerted no influence upon bacterial life, but that in solution it was powerfully antiseptic. When the powder was dusted over open wounds of the skin, from which there was little or no secretion, the admixture of pathogenic germs was speedily followed by infection and the death of the animal. But in sacculated wounds, in which there was an abundant secretion, the iodoform prevented or retarded infection very noticeably. In these cases the iodoform did not remain unchanged, as in the first experiments, but was split up and partly absorbed. The speaker concluded, therefore, that the activity of iodoform was in abeyance as long as it remained unchanged, and that its antiseptic properties were exerted only when its chemical decomposition had begun.

In order to determine how the decomposition of the iodoform was brought about, he added some of the substance to pus containing only the micrococci of suppuration, and protected from any contamination with microbes in the atmosphere. At the end of a few days the decomposition began. A dialyzer, filled with water and placed in the vessel containing the pus, was found to contain new iodine compounds. Then iodoform was added to blood-serum, but it was unchanged even after several weeks. The addition of streptococcus pyogenes and of staphylococcus aureus, in different experiments, caused a splitting up of the iodoform in a short time. From this he concluded that the micro-organisms were the cause of the decomposition.

But as the specimens of pus to which iodoform had been added remained free from odor, the author was led to believe that the ptomaines were the bodies to whose presence the decomposition of the drug was to be attributed. He therefore experimented with cadaverine and other ptomaines, and found that they speedily lost their poisonous qualities upon the addition of iodoform. At the same time the drug underwent chemical decomposition. That the ptomaines were the bodies which caused a splitting up of the iodoform was, he thought, further shown by the fact that the latter could be used only in small quantities in the rectum without producing toxic effects. And again, with certain forms of bacteria, the action of the drug was noticed only after a few days, that is, after ptomaines had been produced.

The conclusions to which Dr. de Ruyter came, as a result of his experiments, were wholly in accord with the teaching of clinical experience, viz., that iodoform is a most valuable antiseptic, limiting the advance of pathological processes by reason of its destructive effect upon the ptomaines, the product of pathogenic micro-organisms. The author's studies had not yet reached the point where he could say what was the nature of the chemical decomposition, or what was the real antiseptic substance to which the effects of the drug were to be attributed. Free iodine exerted no such marked effect, but possibly iodine in a nascent state might have a more energetic action.

THE TREATMENT OF ANEURISM BY BACELLI'S METHOD.

ATTEMPTS to induce coagulation in an aneurismal sac by the introduction of foreign bodies have been made at different times during the last quarter of a century. Horse-hair, iron wire, and various other substances have been used for this purpose. But, although coagulation has been induced in some instances, the patients have, we believe, all died, so that the experiment can hardly be pronounced a success. Nevertheless, in so desperate a disease a desperate remedy is justifiable, and the results of several of these trials have been sufficiently encouraging to give some ground for the hopes that have been entertained of ultimate victory.

Theoretically, the best of these methods is that of Bacelli. It is based upon the early experiments of Hewitt Moore, who introduced fine iron wire into the sac. Bacelli uses, instead of wire, a very long, slender watch-spring. A trocar, one-sixteenth of an inch in diameter, is passed into the sac at right angles to the axis of the blood-current, and through the cannula is pushed the watch-spring, varying in length according to the size of the aneurismal sac. The theory of Bacelli is that the presence of the foreign substance, coiled up within the sac, will induce coagulation, and that subsequently the iron will become oxidized, and then dissolved and absorbed.

In the *Gazzetta degli Ospitali*, of March 16, 1887, is

a report of a thoracic aneurism treated after this method by Professor Saboja, of Rio de Janeiro. The patient was a man, twenty-two years of age, suffering from an aneurism of the thoracic aorta. Three watch-springs, aggregating six feet in length, were passed into the sac through a fine cannula. The operation was followed by no bad results, and the patient seemed to be in a fair way to recover, when, fourteen days after the operation, he suddenly died. The autopsy showed that a rupture of the sac had taken place. An end of one of the springs was found presenting at the point of rupture, but it was thought to have been carried there by the escaping blood-stream, and not to have been the cause of the accident. There was no sign of inflammation in the walls of the aneurism. The springs were found embedded in the clots, and broken into fourteen pieces of various lengths. A second tumor was found which communicated with the aorta by the same opening as the larger aneurism.

The result of this trial, notwithstanding the death of the patient, was sufficiently encouraging to convert the operator into an enthusiastic advocate of Bacelli's method, which he calls the most rational treatment for thoracic aneurism of any hitherto proposed.

NEWSPAPERS AND SURGICAL OPERATIONS.

A CORRESPONDENT has kindly favored us with a very interesting collection of daily newspapers containing descriptions of various important surgical operations. These have been culled from New York, Philadelphia, and Western newspapers, and also from weekly local newspapers in various parts of the country. The variety and wide distribution of these articles gives to them a peculiar interest, for it shows that the outbreak of newspaper surgery is not a local disorder. Perhaps the richest and most numerous contributions come from Philadelphia and the great but wicked city of New York. We have, however, some fine illustrations from Chicago and St. Louis, as well as from smaller cities.

One thing is very evident from the clippings furnished us, and that is, that no city can claim that it is better than the rest. It is plainly not a question of codes, but of medical morals as against newspaper enterprise. Many can remember that the late champion of the Old Code, Dr. John P. Gray, published a whole series of his lectures on insanity, delivered before students at one of the colleges here, in the columns of the New York *Tribune*.

FEET.

"How beautiful are thy feet in shoes, O prince's daughter," sang Solomon, nearly three thousand years ago. But time works wondrous changes, and we fear the wise king could not repeat his compliment, were he living in the midst of us now, without doing violence to his conscience. There is no beauty left in the feet of the princess after she has tortured them for years in the narrow leather case raised up at one end, which we miscall shoes.

The foot has struggled bravely to become something more than a mere base of support, and often a painful one, for the human animal. In our supposed progenitors it was so flexible and handy a member as even, though erroneously, to receive the designation of hand, and the apes were called, by Cuvier, quadrumani. Even in some of the human races at the present day the foot is almost as useful for prehension as is the hand. Thus the New Caledonians are said to run up trees with the agility of a cat by grasping the trunk and boughs with the feet and hands alternately, using the two with equal facility. And the instances of individuals, born without arms or having lost these members in early life, who have been able to write, paint, and perform other tasks requiring precision and accuracy of touch by means of their feet alone, are not unknown. But these rare cases of what might be called compulsory atavism only serve to emphasize the failure of the foot in its attempt to raise itself higher than nature intended it should be raised. The moralist might draw from this a warning for those who are ever striving to do what their limited capacities render impossible of accomplishment.

The size of the foot varies in individuals within wide limits, but the average length among different peoples is pretty constant, and would appear, with certain exceptions, to be an indication of the degree of civilization to which the community had attained. Thus, according to a series of measurements collected from various sources by M. Topinard, and quoted by M. Manouvrier in the "Dictionnaire des Sciences Anthropologiques," we find the proportionate length of the foot to the height of the individual, represented by 100, to be as follows: Parisians, 14.8; Russians, 15.5; Hungarians, 15.4; Chinese, 15.1; Australian Aborigines, 15.1; Algerians, 14.8. The Chicago foot is said to bear a much larger proportion to the size of the individual, and a similar disproportion has recently been affirmed of the pedal extremity of the Bostonian by a popular writer, but neither of these reports is substantiated by scientific measurements, and, coming from lay sources, they are not to be relied upon as scientific facts.

The shoes worn by the majority of civilized men are an abomination. They are wrongly constructed and are the cause of most of the acquired deformities of the foot. The axis of the sole of the shoe should not be a straight line, but should be curved, following the natural curve of the foot, with convexity looking outward. The sole should be of moderate thickness and flexible, and the uppers should fit snugly, but not so as to cramp the foot in any part.

ORIGINALITY AND AMERICAN MEDICINE.

THE query must occasionally arise in the American physician's mind whether the profession of this country is not losing some of the originality and inventive power with which we have been in the habit of crediting ourselves. As a faithful chronicler of all important discoveries, devices, and original views or methods, we are obliged to confess that the study of foreign literature brings to us the richest material. That there should be a preponderance of foreign work is natural, since numerically the profession of Europe exceeds that of the United States, to say nothing of the numerous well-established centres in which opportunities for research are freely given. But even admitting this, it seems just now as though American energies were spent mainly in following out lines of thought, modes of research, or methods

of treatment originated in Europe. Our pathologists are pursuing the study of bacteriology along the lines laid down by Koch, at one time a plain country doctor in a small German town. Our surgeons are trying to rival Tait, Keith, Martin, Billroth, and Schede while following strictly the principles first enunciated by a Scotch professor. The brain is being operated upon according to methods devised by Horsley, and the neurologist furnishes indications obtained from a study of the researches made by numerous English and Continental investigators. Our therapeutists are kept busy testing various German antipyretics, antiseptics, antirheumatics, narcotics, and other drugs in almost innumerable amount.

A thorough and logical advocate of the doctrine of protection might claim that there was good reason why the importation of foreign ideas, foreign methods, and foreign alkaloids should receive a prohibitory tariff. If our physicians and surgeons had no oportunity to experiment with things imported, they would have a little leisure for thinking out new ideas of their own. We would not deny that this is done already to some extent, but remembering that the number of American physicians is about one-third of that in Europe, it seems that the proportion of original contributions to our art is below what it should be.

News of the Week.

The Medical Society of New Jersey.—The next annual meeting of the Medical Society of New Jersey will be held in the Baldwin House, Beach Haven, on Tuesday and Wednesday, June 14 and 15, 1887, commencing at 4 o'clock P.M., on Tuesday.

American Climatological Association.—The fourth annual meeting will be held in Baltimore, Tuesday and Wednesday, May 31 and June 1, 1887, in the hall of the new physical laboratory of Johns Hopkins University, Monument Street, near Eutaw.

The Florida Medical Association held its thirteenth annual session at St. Augustine, on May 23, 1887.

A Case of Yellow Fever was observed at Key West, Fla., on May 21st.

A New Hospital in Harlem was opened in January of this present year, under the auspices of the Commissioners of Charities and Correction. It is to be known as the Harlem Hospital, and it is situated at the foot of East 120th Street. The Hospital contains forty beds, and is supplied with two ambulances. The Visiting Surgeons are Drs. F. S. Dennis and Thomas H. Manley; the Visiting Physician is Dr. J. G. Truax. The House-staff of four are paid a salary of $800, $700, and $600. Dr. Grauer is Pathologist.

Hospital for Paralysis.—We learn that there has been opened in this city a hospital for the treatment of paralysis, which, it is truly stated, is a very prevalent disease. Whether the institution treats paralysis of the eye, throat, bladder, brain, or legs, we are not informed. But an institution for the treatment of "paralysis" must be as extremely comprehensive in its accommodations as it is inexhaustibly philanthropic in its scope.

The Crown Prince Frederick William.—A cablegram from Rome, under date of May 23d, says: "Dr. Mackenzie operated on Crown Prince Frederick William's throat on Saturday. The result was assuring. Professor Virchow made a microscopic examination and does not believe the trouble is serious."

A Surgeon Refused His Fee.—The newspapers give prominence to a dispute between Dr. Marion Sims and Nat. Goodwin, the husband of the late Eliza Weathersby, the actress. Payment is refused on the old ground that "the treatment did no good." Dr. Sims was called in consultation by the attending physician, Dr. T. S. Robertson, who was in doubt as to the nature of an abdominal tumor from which his patient suffered. The result of the consultation, that an operation afforded the only hope of cure, being communicated to the patient, she earnestly requested its performance. The outcome being fatal, the husband claims that the operation did no good and should not be paid for! Under this extraordinary theory surgeons would soon have to abandon their work. Such actions as those indicated above are particularly unjust. Many surgeons undertake desperate operations against their own inclination and even interest, solely to give the patient an only chance. In such cases the attempt to escape the payment of the fee by claiming that "treatment did no good," furnishes an illustration of colossal meanness, beyond the power of dramatic art to exaggerate or even burlesque.

Dr. Edward D. Griffin, of Lynn, died on May 8th, aged forty-seven years. Dr. Griffin was a graduate of the New York College of Physicians and Surgeons.

Dr. W. Hack, Professor of Laryngology and Dermatology in the University of Freiburg, in Baden, was last week found dead, apparently from heart disease, upon his tricycle, which was standing still in the middle of the road near Staufen, in the Untermunsterthal.

Professor Gosselin. — French surgery sustains a severe loss in the death, on May 1st, of Professor Léon Gosselin, Professor of Surgery in the Paris Faculty, and President of the Academy of Sciences. He was sixty-nine years of age.

Punished for Refusing to Give Expert Testimony.—On May 4th the Circuit Court at Lebanon, O., in the case of Dr. Derby against the State, affirmed the decision of the lower court, by which Dr. Derby had been imprisoned and fined for refusing to give expert testimony unless guaranteed the fee of an expert. The circuit court upheld the decision of that of the common pleas upon technical grounds, and without touching the important question as to whether a physician could be compelled to testify as an expert without receiving the fee of an expert. The fact that the doctor voluntarily attended the examination by the coroner made him liable to summons as a witness, in the opinion of the court, without regard to whether his evidence should be in the nature of a knowledge of facts in the premises or of a professional opinion. We are glad to learn that Dr. Derby proposes to carry the case up, and trust that the profession of his State will support him in endeavoring to obtain a final and just decision upon this matter.

Ultimate Results of the Mechanical Treatment of Hip-joint Disease.—Dr. Henry Ling Taylor writes: "On reading over the report of the discussion on Dr. Shaffer and Dr. Lovett's paper on the 'Ultimate Results of the Mechanical Treatment of Hip-joint Disease,' at the New York Academy of Medicine, May 5, 1887, I notice some important errors in the abstract of my remarks. I did not say and do not believe that adduction is 'due to the fact that patients shrank from putting their entire weight upon the perineal band;' such an idea is nothing short of preposterous in my opinion. I said that the peculiar gait of patients wearing the long splint was partly due to their common disinclination to allow the weight of the body to rest fully on the band for more than an instant. For *adduction* crutch and screw, read *abduction* crutch and screw, since these means are employed to produce abduction. I did not say I would use the abduction crutch in every case, but where a strong and persistent tendency to adduction exists; in the majority of our cases it is not necessary to use it."

The Boylston Prize of the Boylston Medical Society, of Harvard University, has been awarded to Mr. Charles L. Scudeler, for an essay on "Congenital Talipes Equinovarus."

A Chair of Laryngology has been created in the Berlin University, and Dr. Bern. Fraenkel has been made Professor.

The Oregon State Medical Society holds its fourteenth annual meeting at Portland, on June 14, 15 and 16, 1887.

The Old Building used by the College of Physicians and Surgeons of this city is to be turned into a business college. Some have hinted that that was what it has been in times past.

By the Will of the late Oliver Hoyt the sum of $20,000 has been bequeathed to the Methodist Episcopal Hospital of Brooklyn.

Dr. Wilson Fox, Physician-in-Ordinary to the Queen, Professor of Clinical Medicine at the University College Hospital, died of pneumonia, on May 3d, in the fifty-sixth year of his age.

"Literary Piracy."—Dr. W. R. Whitehead writes that his article, published first in The Record, and subsequently in the *Provincial Medical Journal* without acknowledgment, was sent to the latter journal by request, and with the understanding that due acknowledgment would be given.

The American Academy of Medicine holds its annual meeting on Friday and Saturday, September 5 and 6, 1887, at Washington, D. C.

Reduced Fare for Delegates to the American Medical Association.—Delegates to the American Medical Association, at Chicago, on June 7th, who go from New York and vicinity, by using the Baltimore & Ohio R. R. can have the privilege of stopping over one train, or almost an entire day, at Washington, and are returned from Chicago via Niagara Falls, thus affording a change of scenery. The rate via this line is $17 going, and $6.67 returning.

The Bill to Regulate the Practice of Medicine in New York State passed the Legislature on May 23d.

An International Congress of Inebriety is to be held in London on July 5th and 6th, under the presidency of Dr. Norman Kerr.

The Late Dr. E. Darwin Hudson.—At a meeting of the Faculty of the New York Polyclinic, held Thursday, May 12th, the following action was taken regarding the death of Professor Hudson: "The announcement of the sudden death of Professor Erasmus Darwin Hudson came upon us with such crushing effect that we have not yet had time to recover from the blow which overwhelmed us. Just entering upon the period of mature middle life, where the student passes from experiment and crucible to philosophic thought and ripe judgment, he was well equipped to reap a rich harvest of new scientific knowledge to add to the general stock; but which is now lost to us forever. His honorable positions of visiting physician to Bellevue Hospital; Chairman of Section of General Medicine in the New York Academy of Medicine; Professor of General Medicine and Diseases of the Chest in the New York Polyclinic, afforded him rare opportunities and gave his wide following of admiring disciples the means for becoming acquainted with, and availing themselves of, the rich store of practical knowledge which he had always so ready at hand. Thus deeply impressed, be it therefore

"*Resolved*, That the Faculty of the New York Polyclinic are sensible that they have lost in Professor Hudson an able coadjutor, a popular, learned, and gifted member, and that the graduate pupils in attendance from all parts of the country have lost an eloquent and skilful teacher; and all of us a genial friend."

At a meeting of the Section of Practice, New York Academy of Medicine, held May 17, 1887, on motion of Dr. Thomas H. Burchard the regular order of business was postponed and a committee of three, consisting of Drs. A. Jacobi, T. H. Burchard, and R. C. M. Page was appointed by the chairman to draft a suitable memorial in regard to the death of Dr. E. D. Hudson, late Chairman. The committee reported the following:

"In the full strength of intellectual vigor and the flood of professional success, E. Darwin Hudson, Jr., A.M., M.D., has closed the volume of his life.

"In an age of rivalries his frank and generous nature, his unsullied integrity and loyalty to truth, made friends of his competitors, and won for him universal esteem.

"In his profession his faithful scholarship and untiring energy secured his elevation to a professorship and his election to the chairmanship of an important section in the New York Academy of Medicine.

"As a man he was true and generous. As a physician he was skilful and wise. As a teacher he was clear, practical, and thorough, his large and enthusiastic classes testifying not only to his personal popularity, but to the value of his teachings. What he said and wrote was not *for* practice, but *from* practice, and his untimely death has robbed his profession of one of the most promising and useful men.

"To the public and profession at large the New York Academy of Medicine desire to give expression to their high appreciation of his worth, and to testify their personal sorrow in his untimely decease. To his family and friends they tender a most sincere and respectful sympathy. R. C. M. Page, M.D., *Sec'y.*"

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 19, 1887.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE Statistical Secretary, DR. A. B. JUDSON, announced the deaths of

LOUIS SCHULTZE, M.D., AND E. DARWIN HUDSON, M.D.

THE PRESIDENT acknowledged the receipt for the library of *three* manuscript letters by the late

E. G. FOUNTAIN, M.D.,

of Davenport, Ia., on the question of the *oxysulphate of antimony* and *chlorate of potash*. It was Dr. Fountain who lost his life from nephritis produced by chlorate of potash through therapeutic experimentation on himself. The letters were written in the autumn of 1859.

The President also presented the letters written by the late Dr. Hudson with reference to the question to be discussed in the Academy this evening.

The Academy adopted the recommendation of the Council, and voted to place the name of

MRS. CELINE B. HOSACK

on the list of *benefactors*.

THE MANAGEMENT OF EMPYEMA, MEDICAL AND SURGICAL.

The above subject was presented by the *Section in Practice*. The discusssion was opened by DR. L. EMMETT HOLT, who read a paper (see p 602) on

THE RELATIVE ADVANTAGES OF ASPIRATION AND EARLY INCISION IN THE TREATMENT OF EMPYEMA IN CHILDREN.

DR. FRANCIS HUBER followed with a paper (see p. 604) on

ACUTE EMPYEMA IN CHILDREN.

DR. ROBERT ABBE then read a paper (see p. 606) entitled

GENERAL CONSIDERATION OF THE SURGICAL TREATMENT OF EMPYEMA.

The discussion was continued by DR. T. H. BURCHARD, who said that his experience was limited to *eleven* cases of chronic empyema, the youngest patient being three years old, and the oldest a man fifty years of age. In all the cases the patients had been subjected to aspiration before the cutting operation, which consisted in making a free incision from one inch and three-quarters to two inches long, usually along the superior border of the eighth rib. The smallest quantity of pus evacuated was *seven ounces*, in a boy seventeen years of age, and the most chronic case which he had seen. The largest quantity of pus evacuated was twelve quarts, drawn from the left chest of a man twenty-eight years of age, three days after an aspiration had removed one and a half pints. The previous health of the patients was good in five cases, delicate in four, and in two there were evidences of phthisis. Three patients recovered entirely, two developed phthisis subsequently, from which they died; one has phthisis now, and one died of dysentery (evidently tubercular), fourteen months after the operation.

HEMORRHAGIC PLEURISY

followed the operation in two cases and proved fatal. Dr. Burchard regarded the hemorrhage as due to capillary oozing, the same as occurs occasionally in old men whose bladders are emptied suddenly while suffering from retention of urine. He advised early performance of the operation to prevent fatal results from diseases liable to develop.

DR. H. N. HEINEMAN contrasted the two conditions —empyema in children and in adults—and pointed out that they differ notably in their clinical history. The disease is common in children, very frequently has associated slight involvement of the opposite lung, and when on the left side is apt to be complicated by pericarditis. Distinct flatness on percussion is not so common in children as in adults, and when he heard distinct cavernous breathing or gurgles close under the ear at a fixed level, he always suspected that he had to deal with pleurisy rather than pulmonary consolidation.

So far as treatment was concerned, he used the aspirator once, perhaps twice, and then if there was not a prompt subsidence of the disease, he made an incision into the cavity. During the last ten years he had used, with very satisfactory results,

THROUGH DRAINAGE.

DR. E. G. JANEWAY said that if the first aspiration failed to afford permanent relief, he advised that free incision be made immediately. There were some cases, however, in which

INCISION COULD NOT BE PRACTISED.

Empyema as a complication of pyæmia could not be cured by incision. Double empyema with pericarditis did not permit incision; and there were cases in which the fluid was septic, where the surgeon was debarred from the operation. He also referred to a case seen in consultation with Drs. E. S. Warner and J. Woodman, one of gangrene of the lung with pyo-pneumothorax, and the foul fluid was so shut in with consolidated lung above that an exploratory puncture made where an incision would have been of service, only made the patient spit up a small quantity of blood. That man is now so well that Dr. Janeway had found it difficult to say which side was affected.

There are cases in which the aspirator will not evacuate the cavity, even though the fluid be such as will flow through the needle freely. Free incision in these cases at the spot where

THE ASPIRATOR FAILED TO OBTAIN FLUID

has allowed a large quantity of sero-purulent fluid to escape without flocculi of fibrin. He was decidedly in favor of *early operation* in preference to aspiration; an incision where, as a rule, a single aspiration has failed.

DR. W. H. KATZENBACH'S experience had been derived, chiefly, in the treatment of empyema in adults. The rules by which he had been guided were to make an exploratory puncture with a hypodermic needle, and if pus was found, to aspirate. If the pus was fetid, he incised, irrigated, and drained the cavity. If the pus was laudable, but reaccumulated rapidly, he would make the incision and drain. Where the pus points externally he endeavors to make an opening at that point, and also a counter-opening perhaps, and either through drainage or irrigate and drain, and treat the case antiseptically. Dr. Katzenbach then referred to a case already partially reported, in which the duration of the empyema was from October, 1878, to February, 1886, in which aspiration was performed frequently, and very large quantities of pus withdrawn.

DR. ALFRED L. LOOMIS had been accustomed to regard pleurisy in children as very different from the pleurisy of adults. Acute suppurative pleurisy in children, according to his observation, was very common, and the management of these cases had been very satisfactory, according to the general rules which had been so clearly set forth by those who had preceded him in the discussion. But

ACUTE SUPPURATIVE PLEURISY IN THE ADULT

was a very different affection, and, according to his observation, it was dangerous in the great majority of cases. He had come to recognize it as an *infectious pleurisy* in almost all cases, and, as a rule, as in children, there is some—perhaps slight—involvement of the

opposite lung. The rapidity with which the cavity fills in these cases is remarkable. He had seen cases in the adult in which the pleural cavity filled completely with pus within twenty-four hours, and it had seemed to him that the withdrawal of the fluid had influenced the course of the disease but very little. If the acute stage could be gotten over, then the case is one of simple empyema, and the complete recoveries that have taken place after that stage has been reached speak decidedly in favor of free incision. But

THE FREE INCISION DOES NOT PREVENT A FATAL ISSUE

during the acute process of the disease. He believed that these cases were fibrinous at the beginning, for the first twenty-four hours, and then the chest fills rapidly with fluid.

With regard to *chronic empyema in the adult*, there was always something behind the pleurisy that must be looked for as the cause of the pus in the pleural cavity. Simply evacuating the pus in these cases, without change of air and medical treatment, was not so likely to be successful as in chronic empyema in children.

Dr. J. West Roosevelt thought that the chances for success with aspiration in children should be better than in the adult, because only the superficial epithelia of the pleura are destroyed in children, whereas the lesion is very much deeper in adults. He then referred to a case of pyo-pneumothorax, in which aspiration was practised, and finally the cutting operation was undertaken as a palliative measure, as there was phthisis of the opposite lung. The patient took ether badly, and he was turned upon his left side, when the heart and respiration ceased, and the pus poured out of the mouth, and the patient was dead.

He was unable to understand why it was that anyone should wish to wash out the pleural cavity, as it was impossible to bring the antiseptic fluid into contact with all parts of it. So far as *perflation* was concerned, he regarded it as

AN EXCELLENT METHOD OF PRODUCING RUPTURE OF THE LUNG.

Dr. A. Caille had operated 22 times—19 in children and 3 in adults. The children were from five to six months old. There were *six* deaths, *fifteen* recoveries, and one case was under treatment. He uses the aspirator needle for diagnosis. When empyema is present, it should be treated just like any other abscess, an incision made, and free drainage established. He was thoroughly in accord with Dr. Abbe's views. He would not use carbolic acid in the thoracic cavity, especially in children, because of the liability to produce its constitutional toxic effects.

Dr. J. E. Winters took strong exception to the statements that pleurisy in children "almost always ends in the formation of pus." Of 90 cases seen by him in the Demilt Dispensary, empyema occurred in only *four*. Of the 86 cases not one terminated in purulent effusion; every case had been followed to its termination, and the termination had been in complete recovery.

He also took exception to the statement that pleurisy with high temperature at the beginning is almost always suppurative. He did not think it was true. There were two cases in his number that required an operation, but the fluid was not pus. He had not seen a case without abundance of serum with the pus, and it was because of that fact that

THE EMPYEMA OF CHILDREN IS CAPABLE OF ABSORPTION.

He had not interfered, except to remove the mechanical effect produced by pressure. He seriously objected to the use of either the hypodermic needle or that of the aspirator, until it was decidedly necessary, because he believed that they tended to the formation of pus. From what he had seen of pleurisy in children with large effusion, termination in empyema was exceedingly rare, and in almost all cases pleurisy could be treated successfully, without the use of the aspirator and without incision. But when it was necessary to operate, he preferred the free incision.

The President said that Dr. Huber spoke of empyema and not of pleurisy, and did not say that every case of pleurisy commenced with chill and high fever, and then turned into empyema. Therefore his statements were not untrue.

Dr. A. Seibert said, with regard to the use of the hypodermic needle, that whenever it was used antiseptically it was absolutely impossible to do any harm. It should be the rule of every practitioner to have a needle which was perfectly clean and a syringe that was not used for any other purpose.

One of the speakers had said that the washing out was not beneficial. He believed that the benefit was due less to the antiseptic fluid than to the force with which the fluid came out and carried with it the flocculent material. He had seen a large number of cases of empyema in children, and he believed that a large proportion of cases are developed by

THE USE OF DIRTY NEEDLES.

He would never treat a simple case of serous pleurisy by aspiration. He believed in tapping every large effusion and removing as much as possible, antiseptically and slowly, and the results will always be good.

Dr. Heineman referred to a case under Dr. Scharlau's care at the Mount Sinai Hospital, where it had been arranged to adopt the "subaqueous" method of drainage. The moment the fluid was let out there came also a quantity of blood so great that the child went into collapse. The doctor at once reintroduced fluid into the cavity, and the child rallied, and from that the case went on as an ordinary case of empyema.

The President spoke of the *severe cough* set up during the operation, which might continue for hours, perhaps for days. Why did it occur, and how was it to be remedied? A case was related in which aspiration had been practised several times with temporary relief, but it came finally to the operation, and when *thirty* odd ounces of pus had escaped the man began to cough, and it could be stopped only by

RETURNING TEN OR TWELVE OUNCES OF FLUID TO THE PLEURAL CAVITY.

He believed that this procedure would be found to be a good method of stopping this distressing cough. This patient coughed every time the cavity was emptied, and the cough ceased when fluid was returned to the cavity. The final operation in the case must be resection of several inches of ribs. He thought it was evident that in this case the cough was due to sudden filling of the blood-vessels, which also carried with it the tendency to bronchopneumonia or œdema, and also a tendency to hemorrhage from the same cause. Cough had been attributed to irritation of the pleura during the operation, but he had been unable to convince himself that it was true.

Dr. Abbe thought it was quite as probable that the cough was reflex in character, as aphonia, disturbances of vision, etc., had been produced apparently by disturbance of the nerves in connection with the pleural surface.

The President: If reflex, why cease when liquid is introduced into the cavity?

Dr. Abbe: The fluid covers the sensitive portion of the pleura.

The President could explain the loss of voice by the sudden development of hyperæmia of the larynx, and the disturbance of vision by the probable anæmia of the brain in consequence of the sudden change in the chest.

The President announced that at the next meeting of the Academy the subject of *Intubation of the Larynx* would be presented in short papers.

Dr. R. C. M. Page, Secretary of the Section in Practice, reported resolutions on the death of Dr. E. Darwin Hudson, prepared by the committee appointed at the last meeting of the Section, Drs. A. Jacobi, T. H. Burchard, and R. C. M. Page, which were unanimously adopted.

The Academy then adjourned.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

First Annual Meeting, held at the Laurel House, Lakewood, N. J., May 17 and 18, 1887.

TUESDAY, MAY 17TH—FIRST DAY—MORNING SESSION.

THE meeting was called to order by the PRESIDENT, DR. E. L. KEYES, of New York, at 11.30 A.M.

THE PRESIDENT'S ADDRESS.

Dr. Keyes, in his address of welcome, first alluded to the circumstances which had led to the formation of the Association. Then, speaking of the objects of the Association, he said he need not enter into the question of specialism as distinguished from general medicine and surgery. That distinction was being made for us by the circumstances of the times. The concentration of labor certainly yielded more perfect results than its general distribution. There was a field ready, and those who wished might enter in and work. Because a man belonged to this Association did not imply that he at all confined his ability to its peculiar line of study; but it furnished to him an arena in which he might develop his ideas and display the work he had done under the keen criticism of minds familiar with the subject-matter treated, and capable of still further refining, by their discussion, the quality of his work and enhancing its value.

DR. F. B. GREENOUGH, of Boston, read a paper entitled

A FEW STATISTICS ON THE COMPARATIVE FREQUENCY OF THE CHANCROID.

He referred to the marked individuality that was given to the chancroid by the text-books, in spite of which the great difference in the statistics by different observers would show that they must have used a different system of classification. Throughout this divergence of statistics, however, two facts appeared. First, that this lesion had diminished in its relative frequency to the true chancre, with the exception of two periods in Paris, that is, during the war and siege (1870–71) and during the Exposition (1876), and that it occurred more frequently in hospital than in private practice. Dr. Greenough's records at the Boston Dispensary from July 1, 1873, to March 31, 1887, gave a total of 1,593 cases, of which 391 were chancroids, 219 true chancres, 931 doubtful, and 52 cases of herpes progenitalis, making the chancroid stand in proportion to other lesions in the ratio of 1 to 3. These records were not satisfactory, as they showed only the diagnosis made at the time of the first visit. In private practice, out of 100 cases seen 10 were chancroids, 63 were true chancres, 13 were doubtful, and 14 were herpes progenitalis, being a ratio of 1 to 10. The diagnosis in these cases was much more reliable. Both sets of cases showed diminution in the frequency of chancroid. The author thought this was due in part to a change in the type of the disease, and a change in the severity of the cutaneous manifestations in syphilis. Herpes progenitalis not having been recognized by earlier writers was undoubtedly often mistaken for chancroid, and probably also a not uncommon inflammation of a sebaceous follicle on the shaft of the penis, and the treatment of either of these lesions by cauterization, universally practised at that time, would make a very good imitation of a chancroid. The fact that the chancroid had just been recognized and described as a local venereal sore, distinct from the chancre, would make it largely sought for at that time.

Dr. Greenough thought that at the present day a virulent bubo was not more frequently seen in connection with a chancroid than with a true chancre, which he considered was due partly to the fact that this lesion was not so frequently initiated by caustics, and he also ascribed the greater variety of the chancroid to the fact that they were no longer manufactured by cauterizing every venereal sore that was not a typical true chancre.

DR. F. R. STURGIS said that, according to his observation in Charity Hospital, New York, and dispensary practice, the number of cases of chancroid compared with those of chancre were diminishing.

Dr. R. W. Taylor, Dr. Hyde, Dr. Morrow, and Dr. Rockwell had observed a diminution in the relative frequency of chancroid to chancre.

DR. HYDE thought the need of time in which to form an opinion whether a given lesion would or would not be followed by the manifestations of syphilis should be more generally recognized.

DR. OTIS did not agree in so general a condemnation of the cautery. When used early it was of benefit, used late it might do harm.

THE PRESIDENT agreed in the remarks made regarding statistics, but he expressed his belief in the virulence of chancroidal pus as compared with ordinary pus. He agreed with Dr. Otis that cauterization of virulent sores within the first ten days was good practice.

THE PRESIDENT read a paper entitled

SUPRA-PUBIC CYSTOTOMY FOR VESICAL TUMORS AND LARGE CALCULUS; A RECORD OF THREE CONSECUTIVE SUCCESSFUL CASES, WITH COMMENTS UPON VESICAL SUTURE, AND A SUGGESTION FOR DRAINAGE.

He advocated supra-pubic cystotomy for vesical tumors, for certain foreign bodies, in cases of very large stone, and in certain exceptional instances for exploration. The method should not be adopted as the usual one in stone. He gave statistics showing that it was especially objectionable in children. He had operated for the relief of large fibro-papilloma, for flat villous growth, and for a large calculus. He described his way of dealing with hemorrhage and of applying the vesical suture. A double curved retractor was exhibited, and a description given of his method of effecting perineal drainage by puncture, probe, and catheter, making only a small perineal incision. The drainage is considered by Dr. Keyes a most essential step in the operation, and the one feature which makes vesical suture safe and likely to be generally effective; while drainage in the perineum avoids one of the discomforts of supra-pubic section, namely, obstinate fistule.

He prepares a No. 30 French red rubber catheter by passing a string through it, the string being knotted inside the tip. This he passes by means of a long probe inserted through a puncture made upon a broadly grooved staff, and by aid of a finger in the rectum, thus entering the draining-catheter through a hole only just as large as itself.

The paper was discussed by Drs. Cabot, Rockwell, Bryson, and Otis.

DR. A. T. CABOT, of Boston, read a paper on

A CASE OF HYSTERECTOMY FOR THE RELIEF OF PYELITIS FROM OBSTRUCTION.

and referred first to a case in which an operation was not performed. The patient died, and the autopsy revealed the fact that the symptoms of obstruction of the ureters which came on late in the history of the fibroid was probably due to settling of the fibroid in the pelvis and contraction of former adhesions while it was in that position.

In the case which was made the basis of the paper the pyelitis occurred as an early symptom while removal of the pelvic tumor was possible. A second tumor, the size of an orange, was felt near the umbilicus, thought to be probably attached by pedicle to the one, the size of a child's head, projecting deeply into Douglas' pouch.

Later the condition of the urine and the character of micturition, pain, etc., pointed to cystitis from pressure. Two weeks later the symptoms were those of probable suppuration in one or both tumors. The smaller abdominal tumor was removed, after which micturition was less frequent. But the appearance of pus in the urine and other symptoms pointed to pyelitis, the condition of the kidney being considered due to pressure of the pelvic tumor. At an operation for its removal it was with difficulty that it could be pushed up into the abdominal cavity, so tightly was it wedged in the pelvis. The adhesions were not important. The uterus was removed with the tumor, only a part of the cervix being left. The patient rapidly regained strength, and wished to return to work. The urine had become almost clear.

In the absence of the author the Secretary read a paper by Dr. George Chismore, of San Francisco, entitled

SOME CASES OF PYELITIS, IN WHICH FREQUENT AND PAINFUL MICTURITION WAS THE CHIEF SYMPTOM.

Two cases in particular were cited to call attention to the fact noted in the books, but not sufficiently emphasized, namely, that frequent and painful micturition might be so pronounced a symptom in pyelitis as to mislead the experienced observer as to the nature of the case, and cause him to address treatment to the bladder alone while the real malady was in the kidneys. In one of his cases, in which frequent and painful micturition was the chief symptom, the man had sustained a violent muscular strain in the region of the kidney, and for some years afterward suffered in the extreme, and was treated for cystitis by some of the most distinguished specialists; but finally the abscess of the kidney discharged and the patient recovered.

In the second case treatment was directed to presumable cystitis, and at the autopsy the kidney was found riddled with abscesses. He asked, how many times has the healthy bladder been subjected to every variety of persistent treatment while disease of the kidneys has gone on, only shown to be present by post-mortem examination?

He believed that in many cases the diagnosis of pyelitis could be made only by exclusion.

Evening Session.

ON HORNY GROWTH OF THE PENIS, WITH EXHIBITION OF A REMARKABLE CASE.

Dr. J. H. Brinton, of Philadelphia, read the paper, exhibiting a specimen, and referring to those on record. His specimen was from a man on whose penis a horn had existed more than four years, having started from a wart. The wart had itched occasionally, and the patient had scratched it for this reason. Gradually it turned into horny substance. It caused no trouble, except mechanical interference with coition. The horn sprang from the base of the glans, at the coronary border, and was attached to both the glans and prepuce; it was one and seven-eighths inch long, one and three-eighths inch in circumference; it was curved forward. A peculiar feature in this particular case was the fact that the horny plate surrounding the meatus almost occluded the meatus, so that the urine passed only in drops. The urethra behind the horny plate was not contracted. The horn was cut off, and the man left the hospital after about three weeks.

The rarity of horny growths upon the penis was somewhat remarkable. He was surprised to find only fourteen cases recorded in English, German, and French literature. A few more cases had been vaguely alluded to. They occurred either as well-marked projecting horns, or as rough, flat, horny plates occupying the glans penis; they were sometimes multiple. The longest on record was three inches.

Dr. Cabot had seen a horn, perhaps the size of the thumb-nail, occupying the dorsum of the glans penis, in a patient of Dr. Bigelow's, about twelve years ago. He could not say whether it had been reported.

Dr. J. P. Bryson, of St. Louis, then read a paper on

THE CHOICE OF OPERATION FOR THE REMOVAL OF VESICAL CALCULUS IN CASES COMPLICATED BY PROSTATIC OBSTRUCTION.

It seemed strange to the author how little influence prostatic enlargement has upon the cutting or crushing operation for stone in the bladder. He believed that very rarely was section made purely for prostatic reasons, that is, with the intention not only of removing the stone, but for reducing the size of the prostate as well, and thus reducing in intensity, at least, the causes which were most active in the production of stone, as well as lessening the sufferings of the patient in after years. Since 1884 he had operated for stone by prerectal section in four cases, all complicated by a large hypertrophic prostate gland, and had had opportunity to observe one other similar case in the practice of a friend. The age of the patients varied from sixty-five to seventy-four years. The operation in each case was successful. In one of his cases he had occasion again to make an incision and enter the tip of his finger, having failed at the first operation to entirely evacuate all the fragments; in two others opportunity to remeasure the size of the prostate was offered during an operation for return of the stone. In one case he estimated the reduction in size of the prostate after the first operation to have been about one-third in its length, and in the other about one-fourth; in none was there now any residual urine of importance. He did not believe that any other operation for removal of the stone would have been attended by so marked reduction in the size of the enlarged prostate.

The President remarked that while the success of the cutting operation in the cases reported by Dr. Bryson as occurring in old people, had been all that one could ask, yet this operation was shown by statistics to have a much larger mortality in the aged than lithotapaxy. Whatever the effect of the cutting operation upon the size of the prostate, he thought we should do the crushing operation first, if it were practicable, as it was much less dangerous, and if it failed to relieve the symptoms to consider afterward the propriety of any other procedure. He regarded Dr. Bryson's paper as very suggestive.

Dr. Bryson said that in none of his cases was the cutting operation the operation of choice. The effect upon the prostate having been noticed, he thought it was worthy of consideration. The discussion was participated in by Drs. Otis and Cabot.

Dr. P. A. Morrow read a paper on

IDIOSYNCRASY AS AFFECTING THE SPECIFIC TREATMENT OF SYPHILIS.

The author first refers to the ample justification of the claims of mercury and iodide of potassium to be ranked as "specifics" in the treatment of syphilis. These agents, when introduced into the organism, directly attack and cause to disappear the organic lesions as well as the functional disorders created by the syphilitic virus. Experience shows, however, that the action of these drugs is by no means constant and infallible—all syphilitics are not equally susceptible to this curative action. The definite peculiarities of constitution which are generally included in the term idiosyncrasy exert a dominant influence in modifying drug action. The therapeutic action of specific remedies is especially subordinated to conditions of aptitude inherent in the individual.

Idiosyncrasy in relation to the action of mercury and iodide of potassium may be manifest in various modes and degrees of intensity: 1. In an abnormal susceptibility to their physiological or toxic effects. 2. In the produc-

tion of incidental ill effects which may be associated with the drug's physiological action, or may take the place of it, constituting an aberration of the drug's typical mode of action. 3. In an insensibility or failure on the part of the system to respond to the curative action of these drugs.

Various clinical examples were given illustrating the foregoing propositions, particularly cases of idiosyncrasy against the iodide so marked that the local and constitutional disorders caused by the drug surpassed in severity the symptoms of the disease itself. In one case under recent observation ordinary medicinal doses of the iodide repeatedly caused a multiform eruption, consisting of pustular, bullous, nodular, and keloidal lesions, attended with the most pronounced symptoms of constitutional "iodism." The specific lesions were much aggravated under its use.

The various expedients which have been recommended to secure tolerance of these drugs by counteracting their ill effects were enumerated in detail, and their comparative value considered.

In conclusion the author suggested that the practical significance of idiosyncrasy and its bearing upon treatment had not received from specialists the consideration its importance demands. The rules of treatment had been rigorously and mathematically formulated—so many months of mercury, and after a certain date recourse to the iodide of potassium, without reference to the immense variance in the constitution and idiosyncrasies of patients, not only in the toleration of those drugs, but in susceptibility to their curative action.

Dr. R. W. Taylor, of New York, related some

OBSERVATIONS ON THE USE OF OIL OF WINTERGREEN IN THE TREATMENT OF GONORRHŒAL RHEUMATISM,

in which he detailed the histories of about twenty cases of gonorrhœal rheumatism occurring in Charity Hospital the past year, in which he had given the oil of wintergreen a thorough trial. In about nine of the cases the disease was of that chronic kind, in old or neglected subjects, in whom no treatmeut could prove of much benefit. In the others the benefit was marked, and most of them after some weeks recovered entirely. The drug was administered in capsules in pretty large doses, varying according to the circumstances. The urethral secretion also became bland under the action of the drug, and disappeared. Other remedies had in most cases been tried with little or no effect.

Dr. Algernon S. Garnett was the author of a paper, which, in his absence, was read by the Secretary, entitled

A FEW PRACTICAL OBSERVATIONS ON THE TREATMENT OF LATE NEOPLASMS OF SYPHILIS.

The author thought it was an error to give fixed doses, especially in the latter stages of syphilis, without due regard to the nature of the case. He believed in removing neoplasms, slight or grave, and considered no patient safe as long as there was the slightest evidence of the disease. The iodide of potassium or mercury should be pushed in every stage of syphilis as far as it could be borne. If cachexia in the latter stage prevented the free use of mercury, tolerance of the drug must be cultivated until the patient could be put under its full influence. Syphilis, he thought, was not a benign disease at all.

The President exhibited a Reverdin instrument which he had modified for the purpose of performing subcutaneous ligation in varicocele in the manner he had described about two years ago.

Wednesday, May 18th—Second Day—Morning Session.

Dr. Keyes was re-elected President, and Dr. R. W. Taylor Secretary and Treasurer.

A paper on

TEMPORARY OVERSTRAIN OF THE BLADDER, PRODUCING CHRONIC RETENTION OF URINE.

was then read by Dr. F. N. Otis (see p. 595).

Dr. J. N. Hyde, of Chicago, read a paper entitled

EARLY SYPHILITIC EPIDIDYMITIS.

The author cited cases which had come under his observation with a view of presenting the negative side of the subject. The following propositions, he thought, rested on fairly sound clinical grounds: 1. A male patient may suffer from blennorrhagic epididymitis on one side, subsequently contract syphilis, yet escape syphilitic involvement of the epididymis. 2. A male patient may suffer from blennorrhagic epididymitis, involving first one organ, then the other, finally acquire syphilis, and escape syphilitic epididymitis. 3. A male patient may suffer from blennorrhagic epididymitis of one or both organs, become so irritable as to exhibit by inflammatory accidents sympathy with successive blennorrhagic attacks, yet throughout a final syphilis betray no sensitiveness to the last-named disease. 4. A male patient affected at the same time with syphilis and blennorrhœa may suffer from an epididymitis, evidently a complication of the last-mentioned disease—namely, blennorrhœa—and yet escape syphilitic involvement of the organ. 5. A male patient may suffer from tuberculosis, subsequently incur syphilis, yet the epididymis escape involvement. 6. A male patient who has suffered from repeated attacks of blennorrhœa, and that lately, may exhibit the typical form of early syphilitic epididymitis.

Dr. A. T. Cabot, of Boston, reported two cases of

PROSTATOTOMY FOR OBSTRUCTION.

In one the operation was followed by almost complete recovery of the function of the bladder. In this case litholapaxy was done on the stone before the operation of prostatotomy. In the other case, although the first result of the operation was satisfactory, a certain amount of incontinence appeared some months later. Dr. Cabot ascribed this to the hypertrophied condition of the bladder, which was sufficient to overcome the constrictor muscle weakened as a result of the incision into the membranous urethra. He queried whether in a case like this, with good evidence of a hypertrophied bladder, and in which the obstruction was a narrow bar, the internal prostatotomy of Mercier might not prove the better operation.

Dr. Keyes read a paper, entitled

A PLEA FOR THE MORE GENERAL USE OF THE NITRATE OF SILVER IN THE DEEP URETHRA, WITH AN IMPROVED INSTRUMENT FOR ITS APPLICATION.

In the full discussion on the paper which followed, most of the members expressed hopes of better results from deep urethral injections of nitrate of silver than had hitherto been generally attained. Dr. J. H. Brinton was one of the strongest advocates of this method, which he had practised extensively. To relieve the discomfort or pain which the patient experienced after treatment by this or other methods, he had the patient stand by the basin and allow a small stream of water to run over the corona of the penis; the relief was almost immediate. Dr. Mastin referred to the practice of Professor Richardson, consisting in injecting a drachm of almost a saturated solution of nitrate of silver into the bladder in gonorrhœa and chronic cystitis.

Dr. R. W. Taylor, of New York, then exhibited

SECTIONS OF TUBERCULAR TESTES WITH BACILLI, AND THE COEXISTENT BACILLI IN THE SPUTUM.

The Association then adjourned to meet next year, time and place to be announced.

A Case of Infantile Eczema of six months' duration was cured by Dr. Meigs in one week with the following: ℞. Unguent. zinci oxidi, ung. petrolati, āā, ℥ ss.; hydrarg. chlorid. mitis, gr. x. M. Sig.: Apply freely.—*Col. and Clin. Record.*

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, held in Washington, D. C., May 11, 12, 13, *and* 14, 1887.

(Continued from page 591.)

THURSDAY, MAY 12TH—SECOND DAY—AFTERNOON SESSION.

DR. R. A. KINLOCH, of Charleston, S. C., presented a case of

PISTOL-SHOT WOUND OF THE ABDOMEN TREATED BY LAPAROTOMY AND SUTURING THE INTESTINES.

J. B——, colored, aged twenty-seven, was admitted into the City Hospital, January 21st, at 7.50 P.M. He had been shot two hours before in the abdomen with a pistol ball (38 calibre). The ball entered one and one-half inch to the left of the umbilicus. There was slight shock. The patient seemed to be comfortable, with the exception of a slight pain on the inside of the left thigh, which was intensified by movement. Pulse, 88; respiration, 24; temperature, 99°. At 10 P.M. half a grain of morphia was given hypodermatically, and shortly afterward anæsthesia was induced by the A. C. E. mixture. Penetration of the peritoneum was first determined, and the abdomen was then opened by median incision. A weak carbolic spray was used. The intestines were examined piece by piece, and wrapped in towels wrung out of a one to ten thousand bichloride of mercury solution. The jejunum presented four wounds, two of entrance and two of exit. The ileum had two wounds. The mesentery was perforated in two places and was also badly torn. There was free bleeding from a mesenteric branch, which was controlled by pressure-forceps and subsequently by ligature of silk. All the wounds were closed with the Lembert suture, using a fine round needle and antiseptic silk. The wounds of the mesentery were brought together, as far as was possible, but there was an infiltration of blood which could not be removed. The abdominal cavity was washed out with a weak solution of hydrarg. bichloride. The abdominal wound was closed with silver sutures, and a large rubber drainage-tube introduced. Antiseptic precautions were observed throughout the operation. The next morning vomiting occurred, and an examination of the wound showed that a suture had given way, and a knuckle of intestine protruded. This was returned and the opening closed. At 5 P.M. the temperature was 102°. Vomiting again occurred, and shortly after midnight the patient expired suddenly.

Autopsy—No adhesion of the parietal peritoneum had occurred. Half a pint of dark, sero-sanguinolent fluid was found in the cavity. All the intestinal sutures had held, and there was no fecal extravasation. A circumscribed abscess was discovered in the meso-colon, out of the line of the bullet. The ball was found behind the body of the fourth lumbar on the left side.

This was the third case in which the author had performed laparotomy for bullet-wounds of the abdomen without visceral protrusion. In two cases of such injury the patients recovered without operation. The first operation was performed May 27, 1863; this patient recovered. The operation was performed seven months after the injury. There had been but one discharge from the bowels, and the patient was gradually sinking. This was the first time that laparotomy was done for gunshot wound without protrusion.

DR. W. W. KEEN, of Philadelphia, gave an account of a case of

PISTOL-SHOT WOUND OF THE ABDOMEN, INVOLVING THE LIVER, STOMACH, SUPERIOR MESENTERIC VEIN, INTESTINE, AND KIDNEY—LAPAROTOMY—NEPHRECTOMY—DEATH ON THE FIFTEENTH DAY—AUTOPSY.

Miss B——, of Vineland, N. J., a girl aged nearly eighteen, shot herself with a pistol, calibre No. 32, at 6.30 A.M., April 1, 1887. Dr. O. H. Adams, who arrived in a few moments, found that the ball had entered over the liver, and after a careful search found it lying under the skin of the left flank.

I saw her at 2 P.M. The wound of entrance was over the ninth rib, four and a half inches above the level of the navel, and three and three-fourths inches to the right of the median line. Skin not burned. The ball was located eight inches to the left of the median line, one and a half inch above the level of the navel. There was moderate tenderness over the entire belly, hepatic dulness not changed, stomach resonant from fifth interspace, no cough, no râles, vocal fremitus normal; renal dulness began at tenth rib on left side, and was the same on the two sides. There was severe pain in the left shoulder. She had vomited a drachm and a half of clear, bright blood, she told me, immediately after the accident. About a pint of urine, the first since the accident, was drawn by the catheter. It was not bloody. Pulse, 104; respiration, 30. No material rise of temperature. As after consultation with Drs. Adams and Bidwell it was deemed almost certain that the belly was invaded by the ball, exploratory laparotomy was advised, consented to, and begun at 3 P.M., and lasted nearly three hours, with every antiseptic precaution. The ball was easily removed, just under the skin. Neither wound could be traced positively into the belly. On opening the belly neither blood nor serum escaped; nor was any extravasated food or fæces noticed. There was no peritonitis. Two fingers were passed in and an effort made to discover the wound of entrance or exit, without any being revealed by touch. The wound was then enlarged and the stomach drawn out. A small round wound near the pylorus was found and was closed by four sutures (Lembert) of the finest iron-dyed silk, a round, ordinary sewing-needle being used. This wound was practically closed by the ponting mucous membrane. As the ball had entered the stomach, search was made for the necessary wound of exit. None was to be found, but the manipulation showed that a small amount of bloody serum existed in the belly, and a large area of extravasation was seen in the mesentery. But little blood had escaped into the peritoneal cavity. The mesentery was carefully torn through and a small artery tied. The chief bleeding came from a hole nearly one-eighth of an inch in diameter in a large vein, so large and lax that at first I thought it the vena cava, but its position just below the head of the pancreas convinced me that it was a large superior mesenteric vein just before it forms the portal vein. After much difficulty I seized it with hæmostatic forceps and placed a lateral ligature of chromicized catgut on it.

The anterior border of the liver had been scalloped by the ball, but as there was no bleeding it was let alone. In addition a large wound in a coil of small intestine in the left flank had been found. Ten Lembert sutures were used in closing it.

Returning now to the stomach, a very careful search was again made for the wound of exit. It was found obscured by a slight coating of blood. This was closed by three black silk Lembert sutures.

A systematic investigation of the entire bowel from the stomach to the sigmoid flexure showed no other wounds. The left kidney was badly lacerated, and was immediately removed by peeling it out of its capsule and tying the pedicle with a stout silk ligature. A rubber drainage-tube was inserted through the wound of exit into the abdominal cavity.

The wound of entrance was cleansed and closed by three stitches, and the wound of exit by two. Sublimate gauze, rubber dam, and a wide flannel bandage completed the dressing.

During the day following the operation suppression of urine was threatened, only ℥ iijss. being secreted. This was quite albuminous. The next day, however, the amount rose to ℥ xxiv. and on the third day to ℥ xl., and

the albumen gradually disappeared. For the first three days nothing was given her except a little cracked ice, ice-water, and a little whiskey and champagne. On the fourth day peptonized milk in frequent but small quantities was allowed, with rectal enemata of the same, and later other liquid foods. Menstruation appeared regularly when due on April 3d, and saw its usual course of four days. On the 8th she had a chill lasting twelve minutes, and the temperature rose to 104°, but as the most careful examination revealed no spot of special tenderness, no dulness, no fluctuation, and, she was almost, it seemed, in *articulo mortis*, it was not deemed prudent to reopen the belly.

The next day, the 10th, she improved somewhat; on the 13th she had another chill with a temperature of 105.4°, had vomited several times, and also had some involuntary evacuations. But as her condition was fair —pulse, 136, temperature, 101.4°—the belly was reopened and explored. The intestines were bright and glistening, and no peritonitis existed.

Surgical bimanual examination revealed no pus or special tenderness at the site of the removed kidney, or, so far as it could be located, at the intestinal wound. No shock followed. The next day (14th) she had two bloody motions, and gradually failed, dying on the 15th day.

The autopsy by Dr. H. C. Smith revealed general peritonitis, except in the pelvis; but no free pus was found anywhere. Only one wound was found in the stomach, near the pylorus, and this was healed, the four stitches being seen in place. The blood in the mesentery was disintegrating and suppurating, though no abscess existed, nor was there any free pus in the peritoneal cavity. The suppuration was chiefly marked along the mesenteric attachment of the intestine. On the other side of the mesentery, corresponding in position to this wound, was a spot in the bowel-wall as large as a five-cent coin, which was gangrenous, and in its centre were two perforations of the bowels. No wound was found except that discovered at the operation. No trouble was found at the site of the removed kidney. Although it was nearly ten hours from the accident to the time when the intestine and stomach were sutured, no intestinal or gastric juice or fluid escaped, though the intestinal wound was so large and vomiting occurred three times.

The kidney, I believe, has never before been removed at a laparotomy for gun-shot wound; but it was clearly the right thing to do. The day following the operation the remaining kidney worked badly, only three and a half ounces of albuminous urine being secreted. But the next two days dispelled all anxiety on this score, the urine rising to twenty-four and forty ounces respectively, and the albumen soon disappeared. The early and marked compensatory enlargement of the right kidney is also of great interest and importance, though, of course, now well known to follow nephrectomy.

Dr. P. S. Conner, of Cincinnati, said that when an operation is required we are all agreed as to what should be done. But the most important point to determine is, when should the abdominal cavity be opened? There is no single symptom or collection of symptoms to be relied upon. If, however, the temperature remains subnormal four, five, or six hours, penetration and perforation may be considered almost certain. Diagnostial laparotomy is admirable in certain cases. Many of these cases necessarily involve legal investigation, and it is a very simple matter to show that death resulted not from the original injury, but from the surgeon's knife. While it is wise to lay down the general rule that penetrating wounds of the abdomen, and still more, perforating wounds of the viscera, should be submitted to laparotomy, at the same time we are not justified in laying this down as a hard-and-fast rule.

Dr. Moses Gunn, of Chicago, thought that we are now all prepared to say that laparotomy under these circumstances is a proper measure to pursue, but the only question is how to make the diagnosis? We have, as has been said, no positive signs of visceral injury. He held that we are fully warranted in saying that we may resort to laparotomy for purposes of diagnosis when we are in doubt.

Dr. T. Richardson, of New Orleans, gave some statistics of the Charity Hospital of New Orleans, showing that in the last five years there had been thirty-one cases of penetrating knife-wounds of the abdomen, of which twenty-four recovered and seven died. There were thirty-three cases of gun-shot wound of the abdomen, with thirteen recoveries and twenty deaths. Laparotomy was performed in one of the fatal cases of gun-shot wound; all the others were treated on the expectant plan.

Dr. D. Hayes Agnew, of Philadelphia, believed that where there is a reasonable degree of evidence that there is a penetrating wound of the abdominal wall, especially if a shot wound, it is the surgeon's duty to make an exploratory incision. We are not to be deterred by the possibility of some legal technicality if the case should come into court. We are to do our duty without reference to the consequences.

Dr. J. Edwin Michael, of Baltimore, read a

REPORT OF A CASE OF VENTRAL HERNIA SUCCESSFULLY TREATED BY OPERATION, WITH A SUGGESTION AS TO THE METHOD OF OPERATING.

A stout woman, forty-five years of age, had a ventral hernia, and on account of the great annoyance experienced in the use of pads and bandages, she insisted on operation. March 15, 1886, a free incision was made in the median line. The sac was carefully separated from surrounding tissues, and was then emptied of its contents and opened. The sac was cut off close to the margin of the ring. Strong silver-wire sutures were passed, a little less than half an inch apart, having a hold of half to three-fourths of an inch. The sutures included the peritoneal, muscular, and tendinous structures only. These were twisted, and perforated shot employed. The wire was then cut off close. The skin and subcutaneous tissues were secured with catgut sutures. The wound united rapidly. In October examination of the wound showed it to be firmly united. The sutures could be felt, but gave no inconvenience. In his remarks the speaker stated that his object in using the wire sutures in this manner was the expectation that they would be surrounded by a mass of cicatricial tissue, making a permanent closure of the ring. As far as he was aware he had used the wire for this purpose without precedent.

A paper on "Prognosis in Sarcomata of the Breast," by Dr. S. W. Gross, of Philadelphia, was read by title and referred to the Publication Committee.

Dr. D. Hayes Agnew, of Philadelphia, read a paper entitled

THE MEDICO-LEGAL ASPECT OF CRANIAL AND THORACIC WOUNDS (SUICIDAL).

The study of this subject had been suggested to him by a recent case occurring in Newport, R. I. The question was as to the possibility of a cranial wound and a wound of the heart being self-inflicted. A colored man was found one morning lying dead under the breakfast-table. He had food in his mouth, and had a wound of the head and of the heart. The coroner's jury rendered a verdict of suicide, and the body was buried. Subsequently it was disinterred and the verdict reconsidered, and the conclusion reached that the man had been murdered. Suspicion then fell upon the son-in-law of the man, who had up to this time borne a good reputation. At the trial five medical experts were called for the prosecution, and their general testimony was that these wounds were incompatible with the idea of suicide. Subsequently the prisoner confessed that he had committed the murder. As this was an important question, the author had investigated it. There are two conditions resulting from injury of the head which would prevent the infliction

of a second injury. These are unconsciousness and paralysis of one or both upper extremities. Injury to the brain is not necessarily followed by loss of consciousness or by paralysis. Many cases were cited to show the truthfulness of this statement. Numerous instances of heart-injury were given in which, after the reception of the accident the individual was able to perform many acts. Cases were also given in which persons, in attempting suicide, had produced injuries of the head and of the heart. As the result of his study, the speaker concluded that it is possible for a ball to enter the brain without destroying consciousness, although for a moment it may cause mental confusion, and that a suicide may shoot himself in the head, and, after a moment, shoot himself in the heart.

In the discussion which followed, numerous cases were related in which the heart or brain had been injured and the individual had lived for some time, and had not been unconscious. Cases were also given in which both a wound of the heart and of the brain had undoubtedly been produced by the individual himself.

Adjourned until Friday morning.

(To be continued.)

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 15 to May 21, 1887.

TAYLOR, MORSE K., Major and Surgeon. Retired from active service May 14, 1887. S. O. 111, A. G. O., May 14, 1887.

WHITE, R. H. Promoted to be Surgeon with the rank of Major, to take effect from May 14, 1887.

HALL, JOHN D., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 74, Department of Colorado, May 11, 1887.

SUTER, WILLIAM N. Appointed Assistant Surgeon, U. S. Army, with the rank of First Lieutenant, to rank as such from May 16, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 21, 1887.

CURTIS, L. W., Passed Assistant Surgeon. Ordered to the Quinnebaug.

BAKER, J. W., Passed Assistant Surgeon. Ordered to the Hospital, Chelsea, Mass.

PRICE, H. F., Surgeon. Ordered to Board Duty, Annapolis, Md.

GRAVATT, C. U., Surgeon. Detachment from Michigan revoked.

LUMSDEN, G. P., Passed Assistant Surgeon. Orders to the Michigan revoked.

SIEGFRIED, C. A., Surgeon. Ordered to the Quinnebaug.

PERSONS, R. C., Surgeon. Detached from the Saratoga.

FARWELL, W. G., Surgeon. Ordered to the Saratoga.

DIXON, W. S., Surgeon. Ordered to special duty, Baltimore, Md.

ROGERS, B. F., Surgeon. Ordered to the Marine Rendezvous, N. Y.

WELLS, HOWARD, Passed Assistant Surgeon. Ordered to the Jamestown.

WISE, J. C., Surgeon. Detached from the Jamestown.

HARVEY, H. P., Surgeon. Ordered to the Iroquois.

WAGGENER, J. R., Surgeon. Detached from the Iroquois.

WHITE, S. STUART, of Frederick, Md. Commissioned Assistant Surgeon in the Navy, May 19th.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 21, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	3
Scarlet fever	68	6
Cerebro-spinal meningitis	3	3
Measles	79	13
Diphtheria	115	63
Small-pox	29	7
Yellow fever	0	0

SOOTHING MIXTURE FOR CONSUMPTIVES.—On page 563 of THE MEDICAL RECORD for May 14th is published a formula, entitled "Soothing Mixture for Consumptives," of which the dose is stated to be "a tablespoonful every two or three hours." A tablespoonful would represent about four and one-half grains of opium. Obviously a teaspoonful is meant.

MINERAL WATERS OF THE UNITED STATES.—We find in the *Therapeutic Gazette* (March, 1887) the following statement, compiled from the report of Dr. A. C. Peale, in the "Thirty-second Bulletin of the United States Geological Survey." In this report Dr. Peale mentions 2,822 localities of mineral springs. "In the Northern Atlantic States there are 405 localities and 637 individual springs; in the Southern Atlantic States, 371 localities and 1,048 individual springs; in the Southern Central States, 1,201 localities and 1,911 individual springs; in the Northern Central States, 601 localities and 1,276 individual springs; in the Western States and Territories, 722 localities and 3,949 individual springs; making a total of 8,821 springs. But a small proportion of this immense number of waters has been analyzed. Thus, out of nearly 4,000 known mineral springs in the Western States, only 132 have been studied by the chemist, and only 18 have been used as health-resorts.

NOTHNAGEL ON BATHS IN TYPHOID FEVER.—In a recent clinical lecture Nothnagel says: "Our views regarding the use of baths have now become clear, and we have returned to what observation had long since taught us, that eclecticism was here the right method. When I look back upon what, as a young man, I saw with Traube, I must say that Traube, without making it out as something essential, carried out in principle what we have come to after twenty years of struggles and turnings aside, viz., that Traube did not treat all his cases after a routine method, after a fixed plan, but that individualizing his cases he treated them sometimes with warm, and sometimes with cold baths. A little scene that I witnessed there I can never forget. I was in Breslau, and in the Lazareth there had to treat some young soldiers, typhoid patients, strong young men. In the case of one young soldier the temperature would not go down in spite of all our efforts. He was put into a cold bath at 16° C. (60° F.) every two hours, the temperature remained at 40° C. (104° F.). A journey accidentally took me to Berlin, I spoke with Traube about this case, and he said to me: 'When you return put the man into a warm bath.' The man was put into a warm bath and the temperature went down. When we see such sharp contradictions, we come to the conviction that there is not *one* method that is alone successful, but that we must individualize."

THE ANTISEPTIC TREATMENT OF GONORRHŒA, which is being strongly urged by several surgeons in this city, is also endorsed by Dr. J. Edmund Güntz, of Dresden. He recommends the use of pencils of flowers of zinc (zinc oxide), made up without fat or any other ingredient.

THE DEFORMITY TERMED "PUG NOSE" AND ITS CORRECTION, BY A SIMPLE OPERATION.[1]

BY JOHN O. ROE, M.D.,

ROCHESTER, N. Y.

THE nose is the central and most prominent feature ot the face; and on its shape, size, and appearance, to a great degree, depends the relative facial beauty of the person.

Physiognomists emphasize the importance of the nose in the category of anatomical conformations that are indicative of special traits of character; and regard it as a measure of force in nations and individuals.

Says Wells: "A skilful dissembler may disguise, in a degree, the expression of the mouth; the hat may be slouched over the eyes; the chin may be hidden in an impenetrable thicket of beard; but the nose will stand out 'and make its sign' in spite of all precautions. It utterly refuses to be ignored, and we are, as it were, compelled to give it our attention."

Even in ancient times much attention was given to its shape and appearance. Among the ancient Persians no man who had a crooked or deformed nose was allowed to sit upon the throne. Cyrus, it is said, had an asymmetrical nose, which was made a thing of beauty through the kind assistance of his emasculated attendants. In order to secure symmetrical and handsomely formed noses, in the children of the royal blood, the eunuchs who had charge of the royal offspring were accustomed to mould their noses into perfect shape (Mackenzie).

Considered from the profile point of view alone, noses are classified according to their shape by students of physiognomy into five main classes:

1. The Roman noses;
2. The Greek noses;
3. The Jewish noses;
4. The Snub or Pug noses; and
5. The Celestial noses.

These classes of noses, considered in the light of the characteristics of the race or class to which they are peculiar, are observed to indicate prominent traits of character, as follows:

The Roman indicates executiveness or strength; the Greek, refinement; the Jewish, commercialism or desire for gain; the Snub or Pug, weakness and lack of development; the Celestial, weakness, lack of development, and inquisitiveness.

"Le nez retroussé" of the French is applied to the Celestial nose, which is simply the pug lengthened and turned upward so as to form a gentle curve from the root to the tip.

The fact that the deductions of physiognomists almost completely harmonize with the anatomical and physiological facts in the case of the last two classes becomes striking, when we consider that those deductions have been made from observation alone.

Mr. Warwick says: "A snub-nose is to us a subject of most melancholy interest. We behold in it a proof of the degeneracy of the human race."

Tristram Shandy's father, regretting his son's misfortunes, remarked: "No family, however high, could stand against a succession of short noses;" and his grandfather "when tendering his hand and heart to the lady who afterward consented to 'make him the happiest of men,' was forced to capitulate to her terms owing to the brevity of his nose."

There are three conditions that may occur during the development of the nose that give it the appearance called snub or pug. They are: (1) Excessive development of the alæ and cartilaginous portions on the end of the nose; (2) a lack of sufficient development, or a sunken or flattened condition of the base and bridge of the nose, while the end of the nose may be but normally developed; 3, the combination, to a greater or less degree, of the conditions just mentioned. This last condition is the one most frequently found.

During development the nose and parts comprising the central portion of the face, as the ethmoid and sphenoid bones, and parts adjacent, are late in developing, and are also the last portions of the face to undergo ossification. At birth the nose, at its base and central portions, is flat and nearly level with the face, but later this depressed line is replaced by a more prominent one as the nose becomes developed. From this it will be seen that anything interfering with the proper development of these parts so as to cause them to remain in their infantile condition, while the end of the nose undergoes due development, will give the nose a snubbed and unsightly shape.

The best developed and most beautiful noses are one-third the length of the face. But noses often vary from this proportion, and in some instances an ill-formed nose is inherited, it being a special family mark. Ribot says, "that of all the features, the nose is the one which heredity preserves the best" ("Hereditary Traits," Richard A. Proctor). But in other instances it is the result of diseased conditions affecting its growth and proper development during infancy and early childhood.

There are many conditions that operate to produce this result. The principal one is obstruction of the nasal passages which cuts off nasal respiration. During the inspiratory act of respiration and deglutition, when the nasal passages are obstructed, a partial vacuum is produced in the naso-pharynx. This suction force, being exerted on the inner side of the yielding cartilaginous nasal tissues, tends thereby to draw them inward, and thus in a corresponding degree retards or prevents their normal expansion and development. This obstruction of the nasal passages may also cause an enlargement or undue development of the portion of the nose below and beyond the obstruction, especially if this obstruction is composed of firm tissues, through interfering with the return circulation. The end of the nose thus becomes engorged, the vessels distended, and a marked thickening of the tissues takes place. The importance of attention to obstructed nostrils in infants, commonly called snuffles, is thus clearly demonstrated.

All chronic affections of the nose, even when unattended by obstruction of the passages, tend to produce by sympathetic irritation more or less congestion of the vessels of the end of the nose, and, by reason of these vessels having less power of resistance, an undue distention of them takes place; the surrounding tissues become thickened, and an enlargement of the end of the nose occurs. This is very commonly observed during the treatment of nasal diseases.

[1] Read before the Medical Society of the State of New York, February 1, 1887.

This diminished resistance of the peripheral vessels explains the effect of alcohol in the coloration and enlargement of the end of the nose in "old topers," which is so often observed. Alcohol produces congestion of, or sends the blood into, the capillaries and terminal blood-vessels. Since the capillaries in the nose have less resistance than the other superficial vessels of the face or other parts, the effect of imbibition is first shown in the end of the nose.

A crooked and wrinkled septum will have the effect to lower the contour of the nose, as well as to cause an undue arching of the palatine vault.

A snubbed appearance may be given to the nose by injuries to its bridge or base, and also by ulceration and necrosis of the bones of the nasal chambers, especially the vomer, resulting in the removal of the support to the centre of the nose, which then falls inward.

The operation for the correction of the deformity under consideration is easily performed, although I can find no record of it, and have no knowledge of its having been proposed or performed.

It may be classed about the same as the operation for strabismus, and, like many other operations, is mainly to improve the personal appearance of the individual.

The operation consists in the removal from the end of the nose that tissue which is in excess, or which is disproportionate in amount to the other portions of the nose. In other words, we are to make the nose symmetrical from one end to the other.

In cases where the bridge is low and undeveloped, if the end is lowered, made smaller, and brought down so that the top of the nose forms a straight line from its base, or junction of the frontal and nasal bones, to the end, the nose ceases to be unduly noticeable or unsightly; and, although the nose will be smaller, it will appear much larger than before by reason of its being symmetrical and proportionate throughout.

The nose does not appear ugly by reason of the fact that its size is disproportionate to that of the face (for noses vary greatly in this respect), but by reason of the disproportionate relations to one another of the different parts of the nose itself.

In those cases in which the deformity consists in an undue enlargement of the end or cartilaginous portion of the nose, while the bony framework is normally developed, it will be seen that the main portion of the nose is straight until we come to the enlarged end, which suddenly tilts upward. Even in this class of cases it is not the end of the nose that really appears too large, but it is the base or bridge that appears too small or depressed.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

This fact is shown by the foregoing illustrations, made from photographs taken in each case shortly before and shortly after the operation.

In Fig. 1 the bridge of the nose appears much lower than it does in Fig. 2, although it is of the same height. This is also true of Figs. 3 and 4.

The expression of the face in Fig. 2 is decidedly different from that of the face in Fig. 1. The same is also true of Figs. 4 and 3. This change is due entirely to the alteration made by removing the excessive tissue in the end of the nose. It will also be observed that in the case of the boy, excepting the nose, the features are the same in both pictures; and so in the case of the girl. This can be very easily demonstrated in the foregoing illustrations by comparing the shapes of the noses before and after the operation.

The operation is performed as follows: We first deaden the sensibility of the interior of the end of the nose by cocaine (general anæsthesia being unnecessary) and then brightly illuminate this part.

If the tissue is to be removed from that portion where the mucous membrane is not too firmly adherent, the membrane should be dissected back, to be replaced after the operation.

The end of the nose is turned upward and backward, and held with a retractor by an assistant; then sufficient of the superfluous tissue is removed or dissected out to allow the nose to conform to the shape that we desire. Great care must, however, be exercised not to remove too much tissue, and also not to cut through into the skin, lest we may have afterward a scar or a dent in the external surface of the nose.

In some cases no after-treatment is required, but in others it is advisable to mould a saddle or splint, as it were, to the top of the nose, so as to make it, while healing, assume the shape we wish to obtain.

In some instances the large and unsightly end of the nose is not due to an excessive tissue but to a malformation of the cartilages of the alæ, bulging outward with a corresponding concavity on the inside.

These noses can be very readily moulded into a handsome shape by cutting, with a small tenotomy knife, through these cartilages, in different places, sufficiently to destroy their elasticity. Then by inserting a silver or hard-rubber tube, of the proper size and shape, into the nostril, and conforming the saddle to the outside of the nose, we have it encased in an outside and inside splint that compels it to conform to the exact shape we desire.

While performing this operation and moulding the nose into shape, we must not neglect to preserve the nasal passages free and unobstructed.

Thus far I have performed this operation on five persons. I have, however, illustrations of but the last two, although all have been successful. With the first two patients it did not occur to me to have photographs of the nose taken before the operation, and the third patient would not permit it.

A Suggestion for the Suppression of the Masturbation Quacks. — A correspondent writes us: "Having repeatedly seen articles in The Record calling attention to quackery and the demoralizing effects of the publications sent by mail, broadcast, to almost every book-keeper, cashier, and to business men generally in the land, and having been consulted many times by young men of this class who have been 'worked' by different parties, I can but observe that articles of this class in The Record do no good unless the profession as a whole is willing to move in this matter and stop the evil. This, it seems to me, can be done only in one way, viz., by calling the attention of the 'Post-office Department' to this use of the mail." Another correspondent states that a certain Buffalo quack floods the neighboring cities of Canada with insanity-breeding literature.

MIDDLE MENINGEAL HEMORRHAGE—ITS TREATMENT BY TREPHINING AND COUNTER-OPENING OF THE SKULL FOR DRAINAGE—WITH REPORT OF A SUCCESSFUL CASE.[1]

By CHARLES A. POWERS, M.D.,

SURGEON TO OUT-PATIENTS, CHAMBERS STREET HOSPITAL.

As a contribution to the subject of cranial surgery, Mr. Chairman, I beg to present the following case of middle meningeal hemorrhage—interesting because of the extensive clot, the implication of the basis cranii, and the employment of an operative measure hitherto adopted but little, namely, a counter-opening in the skull with thorough cranial drainage.

Frank M——, twenty-eight years of age, a native of the United States, a barber by occupation, was brought to the Chambers Street Hospital in an ambulance at 11.55 P.M., November 22, 1886, with a history of having been found in an unconscious condition on the Bowery sidewalk about fifteen minutes previously.

On admission he was comatose and could not be aroused. His pulse was 60 per minute and full, his respiration 15 and normal in character, temperature 98°. The pupils were both dilated, equal, and responsive to light. The plantar reflexes were preserved on both sides. At times the patient would move slightly in bed, but it was not noticed that he moved one extremity less freely than the other. There were no wounds or other evidences of injury to be found on the body at any point. There was moderate hemorrhage in the right auditory canal. The breath had a strong odor of alcohol. About four ounces of urine was withdrawn from the bladder; this was negative in character. An ice-cap was applied to the head, and one-half hour after admission there was a single attack of vomiting. This was free and of a projectile character.

I saw him for the first time at 11 A.M. the following day. His pulse was then 70, respiration 16, temperature 99.5°. He was semi-conscious, and when aroused would give his name and address and stupidly answer questions. He could give no account of his injury; remembered drinking with companions the night before. On being asked to move his arms and legs he would do so, but the movements on the left side were less free than on the right. Pricking the extremities, both upper and lower, with a pin, elicited rather more decided movements on the right side. There was no anæsthesia. The tongue did not deviate and there was no facial paralysis. The pupils were normal. The discharge from the right ear continued; it was now rather more thin and scanty than when the patient was first seen. Careful palpation of the scalp revealed nothing. The disability of the left arm and leg, associated with the discharge from the right ear, led me to suspect intracranial hemorrhage, but I thought it well to delay a few hours in hope that additional symptoms might make their appearance. The external auditory meatus was washed out and packed with iodoform gauze, and the ice-cap reapplied.

During the afternoon his condition was slightly improved, but this was only temporary.

During the night he was restless; there was at times slight delirium alternating with semi-stupor, but the patient could at all times be roused to consciousness.

On the morning of the 24th, thirty-six hours after the injury, the pulse was 80, respiration 18, temperature 99°; the patient was perfectly rational. There was complete paralysis and anæsthesia of the left upper extremity, also a slight degree of fluttering on the left side of the face. The patient said he did not feel a pin-prick as acutely on the left side of the face as he did on the right. The tongue did not deviate; the right pupil was a little larger than the left; both responded to light. There was no

[1] Read before the Section on Surgery of the New York Academy of Medicine, April 11, 1887.

aphasia. The scalp in the occipital and the back part of the right parietal region had a rather "pulpy feel." The serous discharge from the right ear continued, and there was now an area of ecchymosis over the right mastoid about the size of a silver quarter.

In the absence of Dr. William T. Bull, the surgeon in charge, Dr. R. F. Weir saw him in consultation, and he agreeing with me in the diagnosis of meningeal hemorrhage, and concurring in the advisability of operative interference, I proceeded as follows, the strictest antiseptic precautions being observed throughout :

Ether having been given, the head was completely shaved and the bregma located by means of two straight strips of thin bass-wood, the first or alveolar mastoid passing from the alveolar process of the upper jaw to the apex of the mastoid process, the second or auriculo-bregmatic intersecting this at a right angle, and passing through the external auditory meatus to the vertex. Here a point was marked with an aniline pencil, and

Fig. 1.

one and three-quarters inch behind this a second point marked, locating the commencement of the fissure of Rolando. Its termination was found just behind the auriculo-bregmatic line, on a line parallel with the alveolar mastoid, but passing through the apex of the lambdoid suture. From the commencement of this fissure in the median line a line was drawn parallel with the auriculo-bregmatic, and midway between these, about two and one-quarter inches from the vertex, a point was marked on the right side of the head, approximately locating the motor area for the left arm. Here a free crucial incision was made in the scalp, and the tissues found markedly congested. On reflecting back the flaps there was found to be a fissure in the parietal bone. This ran antero-posteriorly three inches from the median line of the vertex, and was about one-sixteenth of an inch wide. Blood was oozing through this fissure. A trephine three-quarters of an inch in diameter was applied over the fissure, rather more above than below it, at a point where a line drawn from the commencement of the fissure of Rolando to the external auditory meatus would intersect the fissure in the skull (Fig. 2, *A*). A button of bone was removed, and a large jelly-like clot discovered beneath it. Bone was taken away by the rongeur forceps over an elliptical area measuring three inches antero-posteriorly by one and one-half inch at its greatest width (Fig. 2, *D*). This enlargement was made from the trephine hole, principally in a direction downward and forward. The clot was now cleared out by the handle of a teaspoon, the finger, and irrigation, and was found to extend over a superficial area measuring six and one-quarter inches from before backward, and three and one-half inches from above downward. At its centre it compressed the brain to such an extent that the dura was one and three-quarter inches from the inner table of the skull. On reaching the dura it was found to pulsate and to be intact ; there were many oozing points, and about opposite the centre of the skull-opening there was sharp arterial hemorrhage. Owing to the distance of the dura from the skull, and the smooth, yielding surface presented by it, it was found difficult to seize the bleeding points. They were finally ligated, however, after being caught up by a clamp, and the cavity thoroughly irrigated with a warm 1 to 6,000 solution of mercuric bichloride.

The fissure in the parietal bone, above mentioned, extended beyond the limits of the incision, both in front and behind, and was not followed out (Fig. 2, *C C*). The large cavity between the dura mater and the skull extended some three inches behind and below the skull-opening. Obviously this cavity would not drain. Accordingly, at the suggestion of Dr. Weir, I trephined a counter-opening for drainage at the lower and posterior limit of the cavity, just above the point where the lateral sinus crosses the lambdoid suture (Fig. 2, *B*). The edges of bone were then smoothed off, the cavity thoroughly irrigated, and a soft rubber drainage-tube inserted through its entire length, emerging at the posterior counter-opening.

There was still some oozing from the dura, and the cavity was moderately packed with strips of iodoform gauze, one yard by one inch. No attempt was made to sew up any of the scalp wounds ; antiseptic gauze was put beneath them at all points, thus assuring perfect drainage. A large dressing of bichloride gauze and borated cotton was applied to the head. The external auditory meatus was irrigated and packed with iodoform gauze.

The operation occupied something over two hours, and at its close the patient's condition was in every way good. He rallied well from the ether, and three hours later the pulse was 104, respiration 23, and temperature 98°. His bowels were moved by calomel, followed by Rochelle salts. An ice-cap was applied to the head, and he was nourished by small quantities of peptonized milk, beef-tea, and milk punch.

He passed a quiet night, and the following morning, November 25th, his pulse was 108, respiration 20, and temperature 99°. He was perfectly rational, and could feebly move the left arm, forearm, and fingers. Sensation was present in them, but was not acute. The face was about as on the previous day ; the pupils were equal. The dressing was removed from the head, and the iodoform gauze withdrawn from the cavity.

The dura had advanced about half-way to the inner surface of the skull, and there was no hemorrhage from it. The cavity was washed out with one-sixtieth per cent. sublimate solution, the drainage-tube was found to be free, and was left in place. The cavity was repacked and redressed as on the day before. The serous discharge from the right ear was decreasing ; the auditory canal was redressed antiseptically.

8 P.M. : Pulse, 80 ; respiration, 20 ; temperature, 99°. Redressed as in the morning ; dura nearly in contact with inner table. Small strips of iodoform gauze simply inserted between dura and margins of skull-opening.

November 26th (forty-eight hours after operation).— Pulse, 106 ; respiration, 22 ; temperature, 99°. Dura and skull in contact and agglutinated by plastic exudation, except at site of the tube and of the iodoform gauze about the margins of the skull opening. Tube removed, and ten strands of carbolized horse-hair substituted. Antiseptic irrigation and dressing. Discharge

from ear had ceased. Sensation and power in left upper extremity was increasing, and now almost normal. Hand-grasp nearly as firm as on the right side. The patient's general condition was in every way good. The bodily functions were normal.

November 27th.—Pulse, 80; respiration, 18; temperature, 99°. Redressed. Five strands of horse-hair removed. There had been, and was at that time, no suppuration whatever.

November 29th.—Pulse, 80; respiration, 16; temperature, 99°. All but two strands of horsehair removed. Patient sleeps a good deal, and seems somewhat stupid. Condition of wound good. Since the day of operation the ecchymosis over mastoid has gradually extended, and now occupies an area 2 × 4 inches, extending down the neck. There are no evidences of suppuration in this. External auditory canal still treated antiseptically.

November 30th.—Drain entirely removed. Pulse, 76; respiration, 16; temperature, 100°. During the past twenty-four hours patient has been stupid most of the time, but has at times had short spells of wakeful delirium. Condition of wound in every way good. Ice-cap discontinued, and patient given potassic bromide—fifteen grains every six hours.

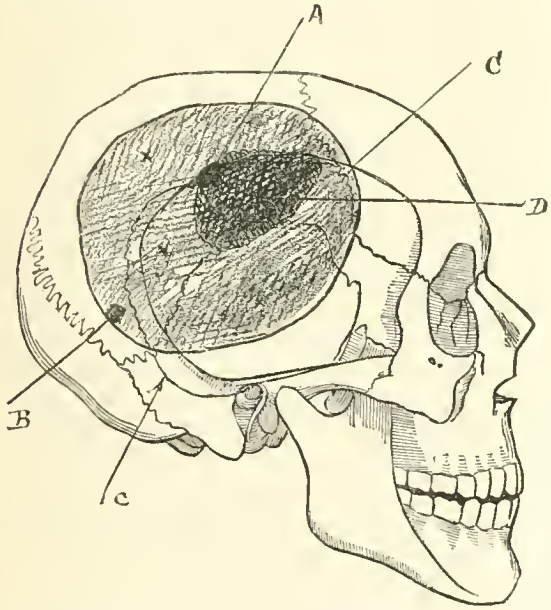

FIG. 2.—Case of M——. *A*, The original trephine opening; *B*, posterior counter opening trephined for drainage; *C*, *C*, fissure in skull not followed out; *D*, area of bone removed; xxx, area of clot.

During the following ten days the patient's temperature ran from 99° to 101°, his pulse was 70 to 90, his respiration 16 to 22. He was slightly delirious most of the time. His urine was normal in quantity and negative in character. No lesions were found in the chest. The wounds of the head assumed a healthy granulating character, with moderate purulent discharge. No pockets could be found. His medical treatment was limited to small doses of potass. brom., tinct. nuc. vom., and dil. hydrochlor. acid.

The delirium and other untoward symptoms gradually subsided, and on December 22d, twenty-nine days after the operation, the patient was up and about the ward. Rational pulse and temperature normal, wound in a healthy granulating condition. Functions of left arm equal to those of right.

Since then his history has been uneventful. At the time of operation the periosteum was elevated from a portion of bone which was not removed, and there is now an area of necrosis about the size of a silver half-dollar (Fig. 1).

The patient is, however, in every way well. As it is not thought best for him to go back to his work until the necrosed bone comes away, he remains in the hospital, assisting the orderly in regular ward duties.

At the time of injury thorough examination of the ears was impracticable, but they have recently been tested by my friend Dr. N. J. Hepburn, whose report I herewith append: "I find in the *right ear* cicatricial tissue over the posterior half of the tympanic cavity, with a fissure in it at the inco-stapedial junction. Malleus present, but displaced backward. H. D.: w., 4″; after inflation, 3½″; tuning-fork, aerial, 8 sec.; bone (mastoid), 15 sec. The bone-conduction, in a horizontal line backward from the 'point of election,' was almost nil, but below was as above given. The *left ear* shows a moderate degree of otitis media catarrhalis chronica. H. D.: w., 30″; after inflation, 40″; tuning-fork, aerial, 35 sec.; bone (mastoid), 15 sec.; improved by inflation. I conclude that the same violence that produced the cranial fracture also ruptured the membrane and dislocated the ossiculæ, and that the hemorrhage may have been entirely due to the middle-ear lesion. The line of loss of bone-conduction in the mastoid would appear to indicate a break at that point."

The subject of middle meningeal hemorrhage has been so fully treated, during the past year, by Jacobson, of London, and Weisman, of Zurich, that I shall content myself with a brief synopsis of its more interesting features.

The sources of blood, in extra-dural hemorrhage, as given by Nancrede, are threefold: First, small vessels between the dura and the skull; second, from the venous sinuses; and third, from the arteria meningea media or its branches.

Of these, the last are by far the most common, and this frequency is rationally explained by the thinness of the bone in the region through which the vessel courses, the fact that the artery channels the osseous structures, and the exposed position of the temporo-parietal region.

Thus, of 31 cases of hemorrhage collected by Mr. Holmes,[1] 27 were from the artery or its branches.

Jacobson,[2] in an exhaustive analysis of 80 cases of middle meningeal hemorrhage, in which there were 69 deaths and only 11 recoveries, divides them into three classes:

In Class A the violence is slight. There is laceration of the middle meningeal or its branches. If a fracture of the skull be present it is slight, and limited to the side of the skull. There is compression of the brain, but little or no contusion of that organ. These cases he considers the most hopeful for trephining. He presents 27 illustrations of this class; of these, 18 were trephined, 9 were not. All treated expectantly died, while of the 18 operated upon 11 recovered.

Class B he considers less hopeful cases. There is laceration of the artery or its branches; fracture implicating the basis cranii—that is, through the middle fossa. There is some injury to the brain, but this is trivial. In this class there are 20 cases, all of which died. (The case of M——, which forms the basis of this paper, would properly belong in this group.)

Class C comprises cases probably hopeless from the first. The violence is very great. There is laceration of the artery or of some of its branches. The fracture of the skull is very extensive, perhaps implicating several bones and sutures both in vault and base. The injury to the brain is very severe. Twenty-three cases, all fatal.

The nature of the injury, or the manner in which it was received, is, I think, of minor importance. By the symptoms alone must we be guided. In hospital practice patients are frequently brought without history, and the surgeon must depend on present and developed evidences in making his diagnosis.

Weisman,[3] of Zurich, tabulates the following symptoms as pointing to middle meningeal hemorrhage.

1. Interval of consciousness between the concussion and the appearance of pressure-symptoms, somnolence, stupor, coma, death. Compression-symptoms may

[1] Surgery, vol. i., p. 575. [2] Guy's Hospital Reports, 1886.
[3] Deutsche Zeit. für Chir., vol. iv., parts 1-3.

appear at any time from fifteen minutes to eleven days after the commencement of the hemorrhage.

2. Hemiplegia on side opposite to injury. This is explained by the position of the artery exactly over the motor centres for the arm and leg. Isolated paralysis of the leg is never observed, but only paresis when the arm is paralysed, or both may be similarly affected at once. Convulsions may precede the affection.

3. Changes in the pulse—infrequency and hardness, generally increasing; sometimes the pulse becomes frequent at the last (paralysis of pneumogastric).

4. Anomalies of respiration—slow, embarrassed, stertorous breathing.

5. Vomiting.

6. Changes of the pupil; generally speaking, dilated pupils point to considerable pressure. The pupil on the side of the hemorrhage may be dilated and may not react.

7. Unilateral impairment of sensation.

8. Aphasia.

9. Disorders of the bladder and rectum.

10. Automatic movements, lying always on one side.

11. Rise in temperature (highest observed being 108.8° F.).

He thinks the diagnosis sufficiently accurate if the first four of these symptoms are present, whether there be a lesion of the skull or not, or even if there be one on the opposite side.

Aphasia, he says, points to an extension of the hemorrhage toward the front; disorders of sensibility to one behind; paralysis of the third pair of nerves to one toward the base of the skull.

This latter symptom, first explained by Mr. Jonathan Hutchinson,[1] is of much importance. Should one pupil be dilated and irresponsive, and should that be on the side opposite the hemiplegia, it would conclusively point to pressure on the oculo-motorius.

To these symptoms Jacobson adds one which I think especially worthy of note, viz.: Ecchymosis or contusion of the scalp in the temporo-parietal or parieto-occipital region, giving rise to a puffy or pulpy feel. This was present in M——.

Given, then, a case in which the evidences point to the existence of a clot, what are the indications regarding treatment? Operative procedures, and at the earliest possible moment. On this point there can be no question.

Roberts[2] says that removal and elevation of bone are needed more for liberation of blood-clot and control of hemorrhage than because of depression of bone.

Weisman presents 257 cases; of these, 147 were treated expectantly and only 12.88 per cent. recovered; of the 110 cases operated upon sixty-seven per cent. recovered; 88 of his cases were closed fractures; and of these, 59 were treated expectantly and only 1 recovered, while of the 29 trephined 9 got well.

We have already seen that in Mr. Jacobson's most hopeful class of cases not one who was denied operative procedures recovered.

In those cases in which the soft parts give no clew to the location of the lesion, where should the brain be uncovered? Fortunately the vessel and its various branches course over and about the fissure of Rolando, and here in almost every instance the seat of the compression will be found. Here, also, are grouped the cortical centres, pressure upon which directs the symptoms.

One mode of locating the fissure has been given in the history of my case, but I may briefly outline a procedure recently advised by Mr. Horsley,[3] and which he believes comparatively free from error.

He locates the upper end according to Thane—*i.e.*, a point one-half inch behind the mid-point of a line drawn from the root of the nose to the occipital protuberance. Hare, of Edinburgh, has shown that the angle which the fissure makes with the mid-line is fairly constant, and is one of sixty-seven degrees. Mr. Horsley accordingly uses an instrument consisting of a long (ten-inch) strip of soft iron, from the middle of which branches off a short (six-inch) strip, the two making an angle anteriorly of sixty-seven degrees. He lays the long arm on the middle of the head, which has previously been marked; the angle between the arms is then made to coincide with the theoretical situation (Thane) of the upper end of the fissure of Rolando; a line drawn down the anterior border of the short arm will now give the situation of the fissure perfectly accurately for the upper two-thirds of its course. He finds that the flexure which the fissure makes in the lower part of its course varies slightly but distinctly in different individuals, and says that no line can accurately determine it. Mr. Horsley does not, however, think accurate location of the lower part important.

Dr. Roberts, in his admirable article on the "Surgery of the Human Brain," already referred to, gives a table showing the exact point, over or about the fissure, which should be opened when any of the various symptoms exist, either singly or combined.

These minute directions must be indispensable when the surgeon seeks a cortical tumor; but in almost every case of middle meningeal hemorrhage the clot will be so large that the surgeon will, I think, meet some part of it if he trephine at the junction of the middle and lower thirds of Rolando's fissure. This view is supported by an analysis of the 80 cases which Jacobson presents; in 68 of these the clot is described as being large, in 6, only, small, while in 6 the size is not mentioned.

Krönlein[1] says that supra-dural hæmatomata may be put in two large classes. The first are *diffuse*, over nearly one-half of the head. The second are *circumscribed*, some part of the dura remaining adherent to the bone. The last have a sharp, well-defined outline, the periphery circular or oval. They are lenticular in shape, thickest at the centre. These circumscribed clots he subdivides into three varieties: *Temporo-parietal*, occupying the middle fossa; *occipito-parietal*, due to laceration of the posterior branch of the artery; and *fronto-temporal*, from laceration of the anterior branch (Fig. 3). He considers the temporo-parietal the most frequent, the fronto-temporal the least. He says that the site of the ruptured vessel determines the location of the hæmatoma, and he gives methodical rules for finding the clot, whether it be anterior, middle, or posterior.

He draws a line through the external auditory meatus and the lower border of the orbit, and calls this the horizontal line of the head. Then he draws a second line parallel with this into the supra-orbital margin, and on this superior line he makes one or two openings, if necessary, in his search for the clot. The first three to four centimetres behind the external angular process of the frontal will discover both the anterior and middle clots; the second opening, which shall be at the intersection of the superior line with a vertical which shall pass just behind the mastoid process, will be over the posterior clot (Fig. 3). Krönlein says: "In any given case in which the surgeon feels sure that there must be a circumscribed clot, let him make the anterior opening, and if he fail to find the clot, let him trephine again posteriorly." He cites four cases, in all of which he trephined anteriorly. In two he found the clot, cleared it out, and cured his patient. In two he failed to find the hæmatoma, and the patients died. In one the autopsy revealed a posterior hæmatoma, which the second opening would have uncovered.

When the clot is found it must be thoroughly removed, all bleeding-points checked, the cavity irrigated and well drained. Bone about the trephine-hole may be removed by the rongeur, over an area sufficiently large to admit of intelligent work in the cavity. Weisman says:

[1] London Hosp. Reports, vol. iv., p. 29.
[2] Annals of Surgery, September, 1885, p. 219.
[3] Am. Jour. Med. Sciences, April, 1887.

[1] Deutsche Zeitschrift für Chir., vol. xxiii, p. 212.

"The main object in operating is to entirely remove the extravasated blood and thoroughly disinfect the cavity which it occupied."

If there be hemorrhage from the dura, it may not be easy to check it. The membrane presents a smooth, yielding surface, which provokingly eludes the forceps. If the dura be near the skull, a needle may be passed under the vessel, but if it be at a considerable depth, as in the case of M——, this is difficult, as one is working through a small hole. Under such circumstances a fine tenaculum will hook up the dura at the site of the hemorrhage, then a blunt forceps may be applied, and the ligature slipped over this.

If the main artery be torn and bleeding below the site of the opening, it would be well to trephine again at a point one and one-half inch behind the external angular process of the frontal bone, and one inch above the zygoma. This will uncover the artery, which may then be ligated. I see no reason why this button should not be replaced. In trephining for pathological conditions, Clark, of Glasgow, and Weir, of this city, have successfully replaced the removed button. Horsley[1] recommends that the bone be finely divided, and then put back between skin and dura.

Persistent oozing from the dura may best be checked by the iodoform tamponade, as in the case of M——, and I call your attention to the fact that in his case the dura and the inner surface of the skull became coated with a layer of plastic lymph, and when they came in contact were agglutinated by it. I have several times packed scalp-wounds in which there was persistent oozing by this iodoform tamponade, and twenty-four hours later found the surfaces coated with lymph, brought them together, and obtained primary union. This procedure was originally proposed by Kocher.

The cavity must be thoroughly drained, and if this is not possible through the original opening, a counter-opening must be made in the skull opposite the most dependent point of the cavity. We would not hesitate to do this in the soft parts, why should we in bony? There is no additional risk to the patient; his danger all lies in a lack of drainage, which, as Weisman says, "results in changes in the extravasated blood which is left in the cranium."

Roberts believes drainage more essential in wounds of the brain than in other structures.

Amidon,[2] of this city, cites 115 cases of trephining, in 20 of which mention is made of free drainage. Of these 20, 18, or ninety per cent., recovered.

Finger and Lee [3] think brain-abscess should be drained as should abscess elsewhere, and report a successful case.

Krönlein says that in diffuse hæmatomata a counter-opening should be made for drainage at the one posterior point which he indicates (marked P, in Fig. 3).

I do not think, however, that any fixed point should be indicated; the counter-opening must be made, as elsewhere in the body, at the most dependent part of the cavity, and the surgeon should not hesitate to make it. Of course, he should not trephine over a venous sinus.

I have been able to learn of but seven previous cases of cranial drainage by a counter-opening in the skull; three of these, unpublished, are from the records of the New York Hospital, and I beg to acknowledge the courtesy of Drs. Markoe and Weir in allowing me to report them.

Case I.[4]—*A case of lodgement of a foreign body in the cavities of the nose, orbit, and cranium, where it remained five months; removal by operation; subsequent trephining for pus in the brain through cranial drainage; death; autopsy.*—Dr. Noyes removed from nose, orbit, and cranium of the patient, a young man, aged nineteen, a piece of iron, four inches and a half long, leaving a hole in the roof of the orbit which would admit the end of the little finger. Drainage between eyelids, moderate suppuration, and on the eleventh day fetid pus evacuated from the brain through the orbital opening. On the fourteenth day patient developed paresis of left forearm and hand, and a counter-opening was trephined three inches above the external angular process of the frontal bone, just in front of the coronal suture. The dura did not pulsate, and pus was found at a depth of three and one-fourth inches. Through drainage, antiseptic irrigation. Pockets of pus and sloughs found all along the track of the tube. The patient retained intelligence, but grew progressively weaker, and died on the thirty-ninth day.

The autopsy revealed suppurative destruction of the orbital surface and interior of the right frontal lobe.

Case II.—New York Hospital, service of Dr. Weir. Necrosis of frontal bone; removal of the diseased bone; dura mater not opened; frontal and suboccipital pains followed, and on the fifth day the patient, a male of forty-five years, was seized with right hemiplegia and aphasia. A hypodermic needle plunged into the dura discovered pus, and two ounces of it were withdrawn from a brain-abscess. Symptoms of compression continuing, a grooved director was passed into the abscess backward and downward to a point one inch and a half behind the ear and three inches and a half above it. Here a counter-opening was made and a drainage-tube inserted. The patient died on the following day. There was no autopsy.

Case III.[1]—Male, aged nineteen. Pistol-shot wound of centre of forehead; course of the bullet traced through the brain; posterior trephining, removal of the bullet through cranial drainage. A rubber drainage-tube was first used, but on the seventh day a composite drain consisting of ten strands of horsehair and four of catgut was substituted for it. Four strands of the horsehair were removed on the fifteenth day. On the seventeenth day it was thought that the removal of the horsehair, as well as the presence of the remaining strands, excited irritation; accordingly they were all withdrawn Hernia cerebri and additional evidences of cerebral irritation appeared later, but these gradually yielded to treatment, and four months from the date of the injury the patient was well.

Dr. Fluhrer concludes that whenever the track of a foreign body can be followed, with reasonable certainty, to an opposite bony point, a counter-opening should be made there and through drainage established, even if the missile be not found. He thinks that a ball, tending in the line of least resistance, would seek that track, and that a later attempt to extract it might be successful.

The following case I report at somewhat greater length as it bears such marked resemblance to my own.

Case IV.[2]—*Subcutaneous fracture of skull; contralateral paresis of face, arm, and leg, with collateral facial paralysis; aphasia; trephining, with counter-opening of skull for drainage on the eighth day; removing a colossal left-sided supradural extravasation; recovery.*—Male, aged thirty, admitted to hospital on diagnosis of fracture of basis cranii. Injury received two days before his admission, at which time there were no external evidences of injury. The patient was fully conscious, but was aphasic. There was left facial paralysis, with occasional facial spasms on the same side. The pupils were strongly contracted, but reacted to both light and distance. There was paralysis, but no anæsthesia of the right arm or leg. The day after admission right facial paralysis came on, but after this the condition remained about the same until the eighth day, when the symptoms in general all became worse, and stupor set in. Firm pressure on the left temporal region seemed to occasion pain.

Krönlein now made a diagnosis of fracture through the left middle fossa and left temporal region, with contusion of the left facial nerve in its passage through the aqueductus Fallopii; supradural hemorrhage.

[1] Dr. W. F. Fluhrer: New York Med. Jour., vol. xli., p. 345.
[2] Krönlein: Deutsche Zeitschrift für Chir., vol. xxiii., p. 218.

He trephined over the middle meningeal artery and found a clot filling the middle fossa, and reaching back to the internal occipital protuberance. The finger in the trephine-opening could not reach the posterior limits of the clot; accordingly, to completely remove the hæmatoma he trephined again at the point marked P, in Fig. 3.

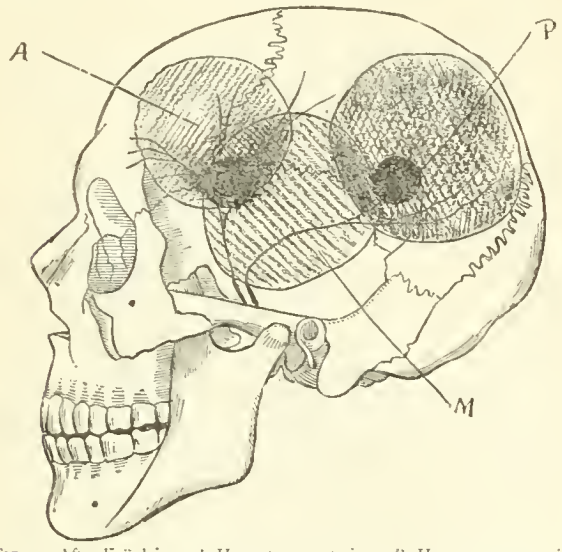

FIG. 3.—After Krönlein. *A*, Hæmatoma anterius; *P*, Hæmatoma posterius; *M*, Hæmatoma medius. The areas in black show the points at which Krönlein would trephine in his search for the clot.

He cleaned out the clot and found the dura uninjured; the cavity, left, measured six inches antero-posteriorly by four from above downward, and at its greatest depth the dura was one inch from the skull. A fissure was found in the field of operation, posteriorly, running downward.

Irrigation with a one-tenth per cent. sublimate solution, through drainage by rubber tubing, large antiseptic dressing applied.

Three hours after the operation the patient awoke and tried to speak. Two days later the facial paralysis disappeared. On the third day the dressing was changed and the dura found approaching the skull. On the fifth day all paralysis was gone, but the patient was still slightly aphasic. On the eighth day the dressing was again changed and the dura found in contact with the skull, except at the site of the drain. Tube removed. On the thirty-second day the wounds were all healed, and the patient completely well except for a resulting diplopia.

CASE V.—New York Hospital, service of Dr. Markoe. S. B——, male, aged forty-eight, admitted May 14, 1885, without history. On admission, left hemiplegia and facial paralysis were present. There was a hæmatoma over the right parietal bone, and on section a fissure was found running backward and downward. He was trephined, and a clot found separating the dura from the skull, over an area five by seven inches. At the suggestion of Dr. Weir a counter-opening for drainage was made three inches behind the first hole. The clot was only partially removed. The cavity was irrigated with a sublimate solution, drainage inserted, and an antiseptic dressing applied.

He became conscious during the operation, and for several days the paralysis steadily lessened. The cavity was washed out daily with a three per cent. carbolic solution. May 16th (two days after the operation), the temperature rose to 104° F., erysipelas appeared on the buttocks, and on May 23d (the ninth day) he succumbed to acute alcoholism and erysipelas.

The autopsy showed a small blood-clot under the dura, but no meningitis.

CASE VI.—New York Hospital, service of Dr. Weir. F. P. W——, male, aged twenty-one; admitted April 20, 1886, with a self-inflicted gunshot wound of the head. The bullet entered one inch behind the external angular process of the right orbit, and came out a little above and behind the same point on the opposite side. Both wounds were enlarged, and two pieces of bullet removed. Bullet-track traversed by a bougie à boule carrying a silk thread, and a rubber tube passed through the brain. Antiseptic irrigation and dressing. The patient retained consciousness, but his temperature steadily rose, and on the second day he died of heart-failure.

The autopsy showed fissure of both orbital plates and extensive laceration of both frontal lobes, especially the left.

CASE VII.[1]—Male, aged forty-four; gunshot wound of head. Bullet entered right squamous bone, passing through the brain and cracking the skull at the left frontal eminence. Both points trephined, the bullet removed; through drainage. Hemorrhage from the inferior longitudinal sinus the following day. Death.

The eighth case forms the subject of this paper.

In the foregoing review of cases in which through cranial drainage was employed, there are five deaths and three recoveries. In no fatal case can the issue be traced, even remotely, to the additional opening, while in each of the others a successful result is due, I think, mainly to its employment.

Regarding the form of drain to be used, soft rubber is the safest and best which we have at present. It is non-irritant, yielding, and efficient. Aseptic horsehair may well be substituted for it at the end of thirty-six or forty-eight hours as the dura approaches the skull. If the cavity is kept thoroughly aseptic these strands may be quickly removed.

In Krönlein's case he left the tube in till the eighth day, but the dura and skull were then in contact, and as the wounds had not been dressed for five days, it is safe to assume that it might have been removed earlier. If the surgeon and all of his assistants work, as they must, antiseptically, I think these cases may well be dressed often at first. Irrigation will surely prevent serous accumulation at any point.

Mr. Horsley, in his exceptionally successful cases of trephining for pathological conditions, sews up the flaps and removes the drain at the end of twenty-four hours; but this is an entirely different condition from the subject under consideration. In the former the dura has been opened, the brain tends to protrude, and Mr. Horsley allows wound exudation to accumulate between the skin-flaps and the brain to exert pressure on the brain. This exudation, he says, organizes and protects the brain in after-life.

Should the flaps be sewn up? Guided by a somewhat extensive experience in the treatment of scalp-wounds, I am free to say that at present I think it safer to leave them open. After all, the cure of the patient is the end we seek, and I think there is less risk in loosely packing the flaps with an antiseptic gauze than in suturing them. In the former case drainage must be perfect; in the latter there may be pockets of pus which can excite mischief. If the patient lives, the wounds will close over, and though healing may be delayed, we shall be satisfied with his recovery. A subsequently increased faith in the infallibility of the antiseptic closure of wounds may probably modify this view.

The prognosis in extra-dural hemorrhage, based on the statistics which I have gathered, has been bad; but I feel sure that in the future, with the steady progress in the physiology of the brain, and the rapid strides now being made in cranial surgery, early and thorough operative procedures will so modify results that this, which has hitherto been deemed a mortal lesion, will be placed high up on the list of curable injuries.

18 EAST TWENTY-FOURTH STREET.

CHILDREN do not like meat until they are five years old.—DELAUNAY.

[1] R. T. Morris: Annals of Surgery, December, 1886.

A REASON FOR MR. TAIT'S SUCCESS IN DEALING WITH SEPTIC ACCIDENTS.[1]

By ROBERT T. MORRIS, M.D.,

NEW YORK.

An incision two inches long, through the synovial membrane of the knee-joint, cannot be made with impunity, unless microbe-destroying agents are employed in a scientific way for preventing subsequent fermentation in the wound.

An incision two inches long can be made through the peritoneum of the abdominal wall almost with impunity, without the employment of antiseptics, if decided cleanliness on the part of the surgeon be observed.

Considering that inflammation beginning at the site of either wound would be due to the growth of micro-organisms, we naturally inquire why it is that nature's methods are so inefficient in preventing extension of the inflammation at the knee-joint, while they are so efficient in preventing extension of the inflammation in the peritoneal region.

We have recently been told by pathologists that when a limited number of certain micro-organisms enter the circulatory system, they are surrounded at once by leucocytes and are not allowed to multiply, and further, that these microbes and their products are discharged quickly from the body along with other blood-rubbish by the excretory apparatuses.

We learn that it is only when certain species of microbes enter the blood in such quantities that the leucocytes and excreting organs cannot easily manage them and their products, that the patient suffers from their presence.

Evidently, then, the lymphatic vessels and the capillaries of the synovial membrane of the knee-joint are not able to remove microbes from that rich pasture with sufficient rapidity, and in a short time the joint-cavity is filled with swarms of the parasites.

The peritoneum, on the other hand, by virtue of its phenomenal absorbing power, is able as a rule to remove the food of the microbes, and to turn the little parasites over to the leucocytes before they have had any opportunity to increase to a dangerous extent.

After an extensive operation within the peritoneal cavity, there is an excessive exudation of fluid from the serous surroundings, and in many cases microbes would increase in this fluid as they do in the synovial fluid, if nature were not aided in her efforts to reabsorb the microbe food.

Mr. Tait's method of aiding nature successfully in this sort of work has not been generally appreciated, but a few quotations from the reports of Wegner's experiments, when placed side by side with some of Mr. Tait's statements, will bring out an exceedingly important point in a clear way.

On page 100 of volume xx. of the *Archiv für Klinische Chirurgie* Wegner says: "Twenty-five cubic centimetres of filtered ichor (Gauche) containing numbers of bacteria were injected into the peritoneal cavity of a healthy rabbit. The animal was killed one hour and fifty-five minutes later. Blood was taken immediately from different parts of the body, and in this blood were found quantities of bacteria. The abdominal cavity was empty. There was mild hyperæmia of the serous membranes. The lymph-vessels of the centrum tendineum were completely blocked up with heaps of bacteria. For persons who doubt that in ichorous peritonitis the ferment organisms enter the circulation in remarkable quantities, there is no more comfortable way of learning something about it than by trying the simple experiment. One finds the bacteria in every drop of blood, look wherever he will, in whatever vessels."

Again, on page 100 (op. cit.), Wegner says: "Twelve cubic centimetres of fluid containing actively moving bacteria and innumerable micrococci were injected into the peritoneal cavity of a medium sized dog. Fourteen days later the dog, having shown no signs of illness in the interval, was killed. Peritoneal cavity absolutely normal and empty. In the heart, in the upper surfaces of the kidneys, and in the marrow, were found minute punctate spots of yellowish color, composed of groups of bacteria and micrococci. In the kidneys some of the herds of microbes lay in the capillaries, especially in the

glomeruli, and some of them lay in the urinary canals." In the fourth edition of his work on the "Pathology and Treatment of Diseases of the Ovaries," Mr. Tait, in speaking of the early signs of septic trouble after ovariotomy, says, on page 314: "For the treatment of the sickness I find the most efficient remedy to be thirty or forty grains of sulphate of magnesia, repeated every hour or every other hour, until the bowels move. . . . As soon as distention is visible . . . I use still more active measures to get the bowels to moving. . . . It is sometimes necessary to use drainage-tubes. Very soon after the wound is closed it will be found that the serum drains from it and the amount of fluid in a short time is simply amazing. . . . My own view about drainage is, that it will be useful only when some addition to this lymph-stream is made, greater than the outlets (natural outlets) can carry away. The fact that I have been so successful in my own operations without drainage makes me think it probable that I have *unconsciously substituted purgatives for drainage* (italics writer's); I find that in very many cases where Keith would have drained, I have purged."

Purgatives, instead of opium, for septic peritonitis after ovariotomy will save the lives of the patients, says Tait with emphasis. (I wonder why he has not assisted with diuretics.) The testimony of the two authors is, therefore, in a nutshell, as follows: Wegner shows that microbes are sent speedily from the peritoneal cavity to the excretory apparatuses, and Tait describes his own successful method of helping on the same work in the cases in which microbes are increasing so rapidly that nature unaided could not deal with them. *Tait's hydragogue purgative, therefore, amounts to a first-class antiseptic measure.*

The majority of operators prefer to employ some other modern antiseptic method, and one which will not only lessen the necessity for purgation, but which will prevent all suppuration in the wounds, notwithstanding the fact that in Mr. Tait's skilled hands his methods of work are so satisfactory.

ON THE DOSAGE OF THE GALVANIC CURRENT.

By A. D. ROCKWELL, M.D.,

NEW YORK.

The more thoroughly one studies electro-therapeutics in all its relations, medical and surgical, the clearer it becomes that the real scientific basis for the use of electricity in medicine and surgery is found in electro-physics more than in electro-physiology. The *rationale*, therefore, of the various methods of electrization, of electro-cauterization, and the important department of electrolysis, can be satisfactorily understood only by those who have grasped the elementary principles of electro-physics —the laws of resistance and conductibility, and, above all, the law of Ohm. Those who have been once well-grounded in these laws of electro-physics, find that the various special problems that arise, whether of a theoretical or practical character, very quickly resolve themselves. I do not propose, however, in this presentation, to discuss the complicated subject of electro-physics, but to offer a few practical suggestions in regard to the important topic of electric dosage. In some conditions and with some individuals the difference in result between a very gentle and short application and a very strong and protracted one is nothing more nor less than the difference between agreeable success and painful failure, while in other conditions and with other individuals the difference between success and failure is measured by the difference between strong and short applications and mild and protracted ones.

There are persons who must be treated not only mildly, but at long intervals; and there are persons with perhaps the same maladies that can bear, with advantage, powerful and frequent applications; to distinguish between these classes and the various gradations that lie between the extremes of tolerance and of susceptibility is the first duty, and oftentimes the hardest study, of him who makes much use of electricity in medicine. To state in definite terms the solution of the problem of electric dosage as it relates to these various classes and gradations is a task that I by no means propose to undertake. The ability to measure with the utmost nicety the strength of the current does not solve the problem.

Such precision may be of the utmost value in the continued treatment of any given case of neuralgia, for example, but the strength then used may in no way answer for the next case, and, therefore, recorded statements of the number of milliampères used in different forms of nervous disease, especially, are by no means as valuable as one might be led to believe.

A clear appreciation of the fact that the human system

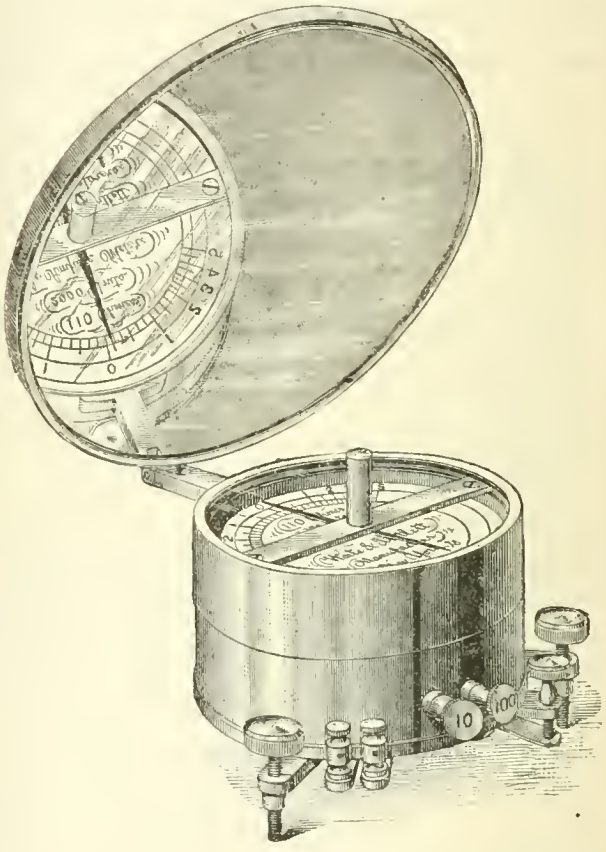

Fig. 1.

reacts to no drug with such varying susceptibility as to electricity is one of the first and most important lessons to be learned.

When we come, however, to the department of electro-surgery as represented by electrolytic action, the case is widely different. To produce certain local effects requires a certain definite expenditure of force, and the question of idiosyncrasy cannot be so much considered, although even here it is not to be altogether ignored.

In a brief consideration of this subject of electric dosage I propose:

1. To describe a new and improved milliampèremeter, and say a few words about current measurement and resistance.

2. To speak of electric dosage in its relation to some nervous disease.

3. In its relation to gynecology and electrolysis.

1. The dead-beat milliampèremeter (Fig. 1) is a great improvement upon anything that we have hitherto had for the measurement of current strength. Those ordinarily in use register but forty or fifty, and oscillate so persistently as to greatly inconvenience the operator.

This instrument, by means of two shunt-coils, will accurately measure as high as five hundred, or as low as one-tenth of one milliampère.

The dead-beat or damping effect is obtained by suspending the needle in a cylindrical block of copper—three times the diameter of the needle. The current in the copper induced by the swinging of the powerfully magnetized needle causes the number of its oscillations to be reduced to three or four, making it possible to take a reading almost instantly.

In ordinary milliampèremeters these oscillations amount to thirty or forty.

The milliampèremeter has been used in therapeutics only a comparatively short time, but for many years nervous as well as other diseases have been treated by electricity, with different degrees of success, according to the individual experience and skill employed in its use. Personally, although acknowledging the great utility of accurately measuring the strength of the current, I cannot claim greater success in the treatment of most nervous diseases, now that the milliampèremeter is employed with every application, than formerly when it was unknown, and this experience is, I fancy, common to all those who have through years of work become practically familiar with the routine of electro-therapeutical treatment. It is, notwithstanding, an immense convenience. It relieves the mind of all anxiety in regard to many minor details, and he who has once tested it will never willingly be without it. To the tyro, however, I am sure that it is a necessity.

Without it he will find himself working entirely in the dark, and a beginner should no more think of attempting serious work without his indicator of current-strength, than he should administer his drugs without his apothecary's measure. Another appliance convenient to have, but in no sense essential, is the rheostat, the utility of which I will briefly illustrate. To-day, for example, the observer notices that the current from a given number of cells is painfully felt by the patient, while to-morrow the same strength applied to the same patient may be felt but slightly. If no milliampèremeter is used, the mystery seems very great, and I know not how many times I have been asked for an explanation.

If, however, the current is measured the mystery is solved, for it is observed that when pain follows the application a greater number of milliampères is registered than when no pain is produced.

All this is explained by the fact that the skin varies very much on different days and in different physical conditions as to its conductibility.

Now if on one day, in an application to a patient of a current from thirty cells, the meter registers thirty milliampères, and on the next the same number of cells, with the electrodes applied on the same portion of the body, causes the meter to indicate but twenty, we know that the patient is offering a far greater resistance to the current on the second day than on the first. It is not essential, for practical purposes, that we know just what that resistance is, but it is desirable and interesting to know, and the rheostat supplies this knowledge with absolute exactness. In order to find out the resistance when the registration is thirty, we substitute a rheostat for the body of the patient and introduce a number of ohms in the circuit sufficient to hold the needle at thirty. If the number of ohms found necessary is three thousand, then three thousand is exactly the resistance offered by the body of the patient on the first day. To find out the resistance when the meter registers but twenty, the same process is repeated, and if the number of ohms registered is five thousand, we know that five thousand ohms is the amount of resistance offered.

The utility of the rheostat in therapeutics is more especially in the direction of enabling us to increase or decrease the current gradually and without shock. After intercalating a resistance of one thousand or more ohms we bring into action the number of cells that will probably be required. By gradually reducing the resistance in the rheostat, the milliampèremeter soon marks the degree of quantity required. To decrease the current the resistance in the rheostat is as gradually increased until the needle points to 0, an indication that the resistance equals the strength of the current. The Germans taught the use of ridiculously weak currents, and, influenced by these teachings and by a natural respect for an agent so subtle, the average degree of strength employed when first I began the use of galvanism, and for years subsequetly, indeed, was in many cases entirely inadequate. In the applications to the head ten or twelve cells were, as a rule, considered quite sufficient. Beneficial results were often seen to follow such mild treatment, it is true, and it was seldom that more was attempted, but that the dose of electricity thus obtained was exceedingly slight, and far more inefficient than was then supposed, can be readily demonstrated. The cephalic electrode was a broad, thick sponge, while the other, applied generally to the pit of the stomach, was of sponge also, but much smaller. The resistance thus offered is necessarily very great, and if the milliampèremeter is used, it will be found that the actual quantity of electricity passing through the body of the patient hardly exceeds six or seven milliampères. Now, to use a current of only this strength in applications to the nerve-centres is, as a rule, little more than child's play, and I make this assertion in remembrance of the fact that I formerly advocated the efficiency of currents even milder than this. Sometimes benefit may undoubtedly accrue from these very mild applications, but I have for so long a time observed the effects of a bolder line of treatment that I have no hesitancy in advocating it in preference to former methods.

In place of a current strength of five or six milliampères, substitute one of twenty, and the superiority of results will soon become manifest. But if, by the method in common use, twelve ordinary cells, in the treatment of the head, deflect the needle but about five degrees, it would take some forty-eight cells to give a strength of twenty milliampères, and few physicians have any such number at command as that. For this purpose the electrodes should be as large as possible—that is—broad, and flat or curved according to the part of the body to which they are applied, but with little bulk.

With electrodes such as these and a series of eighteen Leclanché cells, a current of twenty milliampères can readily be obtained in applications from the head to the solar plexus. Thirty-six cells would therefore give forty milliampères, an intensity of current seldom necessary to exceed in central galvanization.

In making these strong applications to the brain there is an element of danger which cannot be emphasized too strongly, and that is, the possibility and, indeed, the probability, considering the utterly hap-hazard way in which electricity is too frequently used, of the current becoming suddenly broken.

Even with very weak currents applied to sensitive nerves, or to the head, interruptions are as a rule undesirable, and when strong, as indicated by a deflection of the needle of twenty or more, they may painfully aggravate the very symptoms that you are endeavoring to allay. As an illustration of this most important fact I may be allowed to refer to two out of a number of cases upon which this statement is based. The first was a case of epilepsy, one which had been helped, up to a certain point only, by a persistent use of the bromides, but which had very greatly improved and finally recovered, when this treatment was supplemented by galvanization of the brain.

The attacks had been growing far less frequent, and at this time some three months had elapsed since the last. The patient was feeling exceedingly well, and this in itself was with her regarded as a guarantee of exemption; for invariably, before a paroxysm, she was accustomed

to feel far from well. With one pole at the epigastrium and the other on the head I was gradually increasing the current, until it probably indicated some fifteen or twenty milliampères.

In some way the connection was suddenly broken, and, with the characteristic cry, the patient fell over in an epileptic fit, and, as I afterward learned, one of far greater severity than usual. The other was a severe case of chorea, of long standing.

This patient was slowly but surely recovering, and had so far regained command of his lower limbs that he could walk with but slight evidences of any lack of co-ordinating power, and could use his knife and fork with ordinary readiness. About this time he inadvertently received a shock through the head of a current strength of some twenty milliampères. Results of a most unpleasant character followed. The choreic movements of the legs and arms returned in a marked degree, so that he walked with uncertain step, and could no longer feed himself These aggravated symptoms continued for about ten days, and then began gradually to subside. I would by no means be understood to say that a galvanic shock, even though severe, will usually cause marked increase of symptoms that are subsiding under the use of an uninterrupted stable current. Such shocks are many times given without any apparently evil results. They should, nevertheless, be guarded against in every possible way, as their tendency is undoubtedly harmful. One of the diseases to which I will refer in giving more definitely my own experience in regard to electric dosage, is epilepsy, a condition in which electricity is far from being generally recognized as capable of any special service. I am not aware that in this connection the disease has been discussed in any treatise or article excepting my own. As far back as 1878 I wrote upon the subject, and only lately gave, before the New York Academy of Medicine, the results of my observation in twenty-eight cases.[1] Of these twenty-eight cases of epilepsy almost all of them were treated without the aid of accurate current measurement, since the milliampèremeter in therapeutics is of comparatively recent introduction. It is, however, possible for me to give approximately the strength of current used in most of these cases.

The range was between fifteen and forty milliampères. I have found no patient suffering from epilepsy who could not endure, without ill effects, a current of fifteen milliampères, provided the cephalic electrode covered a surface sufficiently large and was accurately adjusted, while most of them bore without discomfort a much stronger current. Seldom, if ever, should I regard more than forty milliampères desirable, and the strength that I have found most generally acceptable, and of service to my patients, has been from twenty to thirty milliampères. In chorea, substantially the same rule prevails in regard to strength of application, or would prevail, if the average age of choreic patients was not much less than that of epileptics.

The strength of current applied to the head in a case of chorea under twelve years of age should rarely exceed twenty milliampères, and generally should be about fifteen. We cannot approximate the relative dose of electricity for different ages as accurately as we can that of drugs. This observation, however, will be found to be uniformly correct : The very young bear proportionately very much stronger currents than adults. A child of three, who should, according to rule, tolerate only about one-fifth the adult dose of any powerful drug, will easily bear one third the adult dose of electricity.

Old people bear stronger currents than those in middle life ; it is, indeed, quite astonishing to observe the very marked insusceptibility of some very old people to electricity, due in some measure, perhaps, to blunted sensibility, but in a higher degree to a loss of conductibility of the tissues, and especially the skin. It will not answer, however, to presume too much in the application of electricity to the old on account of this apparent insusceptibility, as it is not uncommon to meet with patients advanced in years who, while they may feel the application of a certain strength of current but little at the time, yet are exceedingly susceptible to its secondary effects. Another disease for the relief of which the galvanic current is but indifferently appreciated is exophthalmic goitre. Without it, indeed, it is often impossible to obtain results at all satisfactory, but with it marked amelioration of the symptoms almost invariably follows, and complete recovery, many times, in cases that respond but slightly to other methods. The strength of current indicated varies according to the position of the poles. An important point for local application is the auriculo maxillary fossa, immediately below the lobe of the ear, where but a comparatively small electrode can be used.

A strong current would produce both pain and vertigo, and five to seven milliampères is about all that will be well borne with the electrodes in this position.

As we gradually move the pole down along the inner border of the sternocleido-mastoid muscle, the strength can be increased very materially, and with a large pole at the back of the neck, near the sixth cervical vertebra, and the other on the enlargement, currents of twenty and thirty milliampères can be profitably utilized. The variation of current strength in the treatment of neuralgia and pain in general is as wide as the symptoms are varied in character and seat, and more, perhaps, than in disease in general is it necessary to carefully discriminate in the selection of the proper current.

True neuralgia (pain directly along and confined alone to the course of a nerve) calls almost invariably for the galvanic current, while the so-called pseudo-neuralgias, which are simply forms of pain occupying certain areas, and running seemingly in the direction of certain nerves, yield most readily to faradism.

Five to ten milliampères are, as a rule, amply sufficient for the relief of neuralgia about the face and head, while in sciatica it is often necessary to use as high as forty and fifty, or even more. The efficacy of very strong currents in the treatment of sciatica should be more generally recognized.

As ordinarily used it often fails to relieve, because of an insufficient current. The operator is simply self-deceived. He is using perhaps a large number of cells, freshly and properly charged, but his electrodes are of a pattern and size to offer the greatest possible resistance. Let him substitute electrodes that are broad and flexible, readily adapting their shape to every inequality of surface, and this difficulty of lack of strength will quickly resolve itself. In the treatment of paralysis, whether central or peripheral, the dose of electricity is determined by so many modifying factors that it cannot be fully discussed here. The general law, that when a muscle fails to respond to the faradic current recourse must be had to the galvanic, is now usually appreciated, but it is not so generally understood that paralyzed nerves are not to be indiscriminately stimulated by sudden shocks. Many a paralysis that might have recovered has been made permanent by such ill-directed and culpable interference. After it has been determined, by careful interrogation of the affected muscle, what is the degree of quantitative or qualitative change, it is in many cases imperative to use the continuous and not the interrupted galvanic current Especially is this true in those cases of local paralysis where responses utterly fail to be elicited by the faradic current, but are *more* readily obtained by the galvanic current than in the normal condition of nerve and muscle. In such cases mild currents of about seven milliampères, increased to twelve and fifteen as improvement increases, and applied without interruption, will succeed in lessening the irritability of muscular fibre and in restoring the lost vitality of the intramuscular nerves, upon

[1] New York Medical Journal, April 16, 1887.

the integrity of which the faradic current depends for its ability to call forth muscular contractions, far more effectually than when interruptions are attempted.

In most forms of paralysis, however, much stronger currents than these can be applied. In infantile paralysis fifteen or twenty milliampères may be used, and in the spinal paralysis of adults (poliomyelitis) twenty-five to thirty are usually indicated. In both these conditions, but more especially in infantile paralysis, the same rule should be observed as in the treatment of the form of facial paralysis to which allusion has been made—for the most part, continuous and not interrupted currents. Given a case of infantile paralysis in which reaction to faradism is entirely lost and only faintly appreciable to galvanism, it is entirely possible, by sudden shocks in the beginning, to quite obliterate the little remaining vitality and render the case incurable. In hemiplegia, again, while

Fig. 2.

electricity possesses but a limited value, it is yet capable of doing decided harm. I have at this time under observation a hemiplegic patient whose arm was in such a condition of heightened irritability that contractions to both currents were called forth far more readily than in health. He fell into the hands of one who possessed greater activity than insight, and was subjected to a series of treatments by the faradic current in which the muscles of the arm were jerked about in a most merciless manner. As might have been expected, there soon supervened an entire loss of motility, together with neuralgic pains of a distressing character. In alluding to epilepsy and chorea I spoke of central galvanization and its dosage in those diseases. Central galvanization is also a valuable method in many neurasthenic conditions, in hysteria, and in cases ot melancholia. I illustrate in Fig. 2 the process which has given me most satisfaction.

The hair being thoroughly wet, a light wire-gauze helmet, lined with some soft, conducting material, is fitted as accurately as possible to the head. To this is attached the positive pole, while the negative is applied to the pit of the stomach, and a current passed varying according to the disease and individual idiosyncrasies from five to forty milliampères.

It may seem an easy thing to make use of central galvanization satisfactorily, but, like most easy things, its efficient use demands knowledge, care, and some experience, all of which are within easy reach of those who desire to utilize the method. The wide area which this helmet-electrode covers lessens by just so much the resistance to be overcome, and enables us to pass through the head a current of many milliampères, without pain or other ill results. To this end, however, the electrode must be made to adjust itself accurately to every inequality of surface, otherwise a painful concentration of current will be felt at various points, and the efficacy of the applications interfered with.

Any discussion of the subject of electric dosage would be incomplete without reference to gynecology, in which electricity has accomplished much good. Here, more than in any other department of medicine, is illustrated the great superiority of strong, and comparatively short, over weak and prolonged applications.

Much of the ill-success that formerly attended the treatment of female diseases by electricity was due to the use of too feeble currents, and the same misapprehension as to its actual working power alluded to when speaking of central galvanization exists here. With the ordinary form of small, and comparatively thick, sponge-electrode applied externally to the abdomen, and the other internally, a current from thirty-six cells will cause the galvanometer to register but twenty or twenty-five milliampères.

A current of this strength is entirely insufficient to successfully treat many uterine difficulties that experience has shown to be amenable to electrical applications, and, in order to obtain the requisite strength without resorting to the great number of cells that would ordinarily be required, electrodes of an entirely different pattern are necessary. I have for some time used an abdominal electrode similar to the one represented in Fig. 2. It was made for me by Waite & Bartlett, of this city, and can be prepared of any form and size, suitable for application to every portion of the limbs and trunk. Like the helmet-electrode, it is made of finely plated wire, and a layer of absorbent cotton used, sufficient to cover both its face and back, for the more completely a metal electrode is enclosed in its covering the greater is the quantity of current that can be utilized. Apostoli, whose experience has probably been greater than any other in the electrical treatment of the uterus and its appendages, uses electrodes made of sculptor's clay, held in place by gauze, and sufficiently large to cover much, and sometimes the whole, of the abdomen. The principle involved is simply this—the larger the electrode the less the resistance, and, other things being equal, an electrode of six square inches will yield but one-half the strength of current of one of twelve square inches.

In the treatment of uterine diseases it must be remembered that the internal is the effective, while the external is the indifferent or dispersing, electrode.

Bearing in mind, also, that the genital mucous membrane is remarkably insusceptible to painful impressions, while the skin is the reverse, the necessity of large, flexible electrodes that can be accurately adjusted is readily appreciated.

In the treatment of indurations and enlargements of the uterus, and the exudations resulting from pelvic cellulitis, direct applications frequently result in complete recovery. Currents of from thirty to fifty milliampères are indicated and should not cause the slightest pain. On the contrary, there is often instant relief afforded to an ever-present pain, as well as the more remote results as seen in the correction of painful menstruation. This is the safest and easiest method.

More rapid results follow electro-puncture, through which we get in more concentrated form electrolytic and absorbent effects. With the needles, fifty to one hundred milliampères can be used at each sitting.

If the metal electrode is applied directly, without the intervention of some covering, care must be taken not to use currents sufficiently strong to produce eschars. This mishap may occur even without the knowledge of the patient, and it is, therefore, always safer to use a covered electrode. I have seen this treatment, judiciously

and persistently carried out, melt away, as it were, not only large pelvic deposits, but in two instances dissipate a most severe and chronic sciatica that had been caused and continued by the pressure of these pelvic deposits.

In ovarian and fibroid tumors the electrolytic method is undoubtedly worthy of consideration, although the results have not as yet been sufficiently satisfactory, in ovarian tumors at least, to commend themselves strongly to authorities in the department of uterine surgery.

It is perfectly safe to use currents of one hundred and one hundred and fifty milliampères in the treatment of uterine fibroids; indeed, both Apostoli, of France, and Englemann, of this country, claim to use with advantage much stronger currents than this. Whenever, in the use of electrolysis, our aim is simply destruction, and destruction only, I see no reason why a current of even several hundred milliampères might not be freely used. It must be remembered, however, that some of the best results of electrolysis are not measured by the degree of chemical action, and that when various external tumors, such as goitre, disappear under electrolytic action, it is through a process of absorption that is set up, and not because of the destruction of tissue. In the treatment of goitre currents of forty milliampères are indicated. Absorption is hastened by the chemical changes that occur, and takes place both during and after the treatment. In most cases it is not at all observed during the operation, but goes on slowly for weeks following. Stimulation of absorption is especially marked when electricity acts on hydrocele and small cystic tumors. For their treatment a current of thirty to forty milliampères is required. In erectile tumors, where the object is to coagulate the blood, we use about the same strength as when treating cystic tumors.

AMPUTATION OF THE BREAST UNDER COCAINE ANÆSTHESIA.

By DANIEL LEWIS, M.D.,

SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL.

A PATIENT was admitted to hospital March 17, 1887, who furnished the following history:

Mrs. K——, widow, seventy-eight years of age, always healthy until fifteen years ago, when the right clavicle was fractured, and the breast of the same side considerably bruised. After the immediate effects of the injury disappeared she noticed a lump in the breast which has never disappeared, although smaller at times and at other times larger. Four years ago an ulceration began, and on admission was about two inches in diameter. The discharge has increased, and for several weeks hemorrhages have been frequent, although readily controlled. The entire mammary gland is involved in the tumor, which is not adherent to the chest-wall however, nor are there any diseased glands in the axilla. She is quite feeble from loss of blood, and has a double cardiac murmur. There is no family history of cancer.

Here was presented a case where the removal of the tumor was demanded, and yet the advanced age and general condition of the patient rendered the administration of ether positively dangerous. It was therefore decided to attempt amputation of the breast under cocaine, although, as far as could be learned, the operation had never been performed under local anæsthesia.

On March 27th Dr. J. Leonard Corning applied one of the largest rubber-covered iron rings which he has devised for retaining the injected solution within the area of operation. The ring was made elliptical, and would have answered our purpose a little better if made of flexible material, so as to be readily adjusted to the convexity of the chest. The line of incision was traced by tincture of iodine, and injections of a two per cent. solution of cocaine *into* the layers of the skin were made, at intervals of about one-half inch, entirely around the tumor. The patient felt only the first insertion of the needle. Several larger injections were also made beneath the tumor. Less than three drachms were required.

There was no pain during the operation until after the ring had been removed and the last of the sutures were being applied, when she felt the needle in a small section of the lower flap only. There were no after-symptoms due to the anæsthetic. Twenty-five minutes were consumed by the operation. The wound was closed with the continuous horse-hair suture, which I always use for such operations, and drainage of the same material. Healing was complete in ten days.

The result of this case was sufficiently satisfactory to warrant recommending cocaine anæsthesia in any such operation where ether is contraindicated, and there is no necessity of opening the axilla. In the latter event it seems probable that some modification of Dr. Corning's ingenious apparatus could be easily adapted to the requirements of that region.

62 PARK AVENUE.

Clinical Department.

NOTE ON EMPYEMA.

DR. M. PUTNAM-JACOBI, of New York, writes: "In connection with the discussion recently held at the Academy of Medicine on empyema, the following case may be of interest: A child, five years of age, after an attack of scarlet fever, contracted an empyema of the right pleura. The diagnosis was made by the attending physician, but the mother refused to allow an operation, and the case dragged on for six or eight weeks. During this time the patient suffered from attacks of localized œdema, confined to one limb, and constantly shifting from the upper to the lower extremities, and from one side of the body to the other. There was occasionally some œdema of the abdominal walls; none of the face. The urine remained free from either casts or albumen. I saw the patient only once, twenty-four hours before death. At that time the right leg was markedly swollen and œdematous. The right pleura was evidently full of fluid; the condition of the child markedly cachectic. An operation was again proposed, but for some reason either again refused or postponed till the following day. On this day the little patient died. At the autopsy was found, besides a pleural cavity full of pus, a large thrombus in the right iliac vein, evidently the cause of the œdema of the right leg. It became then also evident that the temporary localized œdemas observed during the illness had been due to similar temporary obstructions of the principal vein of the limb. This spontaneous coagulation of blood was due to absorption of the fibrine ferment from the mass of pus, and a consequent action upon the fibrine factors of the living blood, such as usually only occurs after death."

SUBACROMIAL DISLOCATION OF THE HUMERUS.

DR. THOMAS L. STEDMAN, of New York, sends us the following communication: "The case herewith presented appears to me to be worthy of record by reason of the rarity of posterior dislocations of the shoulder, and also on account of the age of the patient. Barbara ——, eighty-four years of age, an inmate of the Home for the Aged of the Little Sisters of the Poor, is of spare build, but in good general health. One morning, while dressing herself, sitting on the bed, she stooped over to pick up her shoe, and fell, striking, as she says, the right arm between the elbow and the shoulder. She experienced at once severe pain in the shoulder, and was unable to move the arm. I saw her about seven hours after the accident. Examination at that time revealed a round, hard projection, like a ball, posteriorly, on the dorsal aspect of the scapula, near its outer extremity. Motion was imparted to the swelling on rotation of the arm, but no crepitus

could be obtained. There was a marked depression below the extremity of the acromion process, and in front of the shoulder-joint, between the coracoid process and the shaft of the humerus, a wide interval was to be felt. The arm hung by the side with the elbow a little in front of the axillary line. It was possible to approximate the elbow to the side when the tips of the fingers were brought to the opposite shoulder. Dr. Joseph O'Dwyer saw the case with me, and kindly assisted in the reduction. The latter was easily effected by downward traction, counter-traction being made with a towel in the axilla. The arm was carried in a sling for a few days, and no further trouble was experienced beyond a slight soreness on attempts at extended movements."

THE LOCAL TREATMENT OF DIPHTHERIA.

Dr. J. Henry Fruitnight, of New York, sends us an interesting communication on this subject, which the crowded condition of our columns compels us to present in abstract. As the disease presents both local and constitutional symptoms, we ought, he argues, to treat it both locally and constitutionally. Many of the remedies employed exert a local effect as they pass over the parts while being swallowed, and, in order to increase this effect, he advises patients, who are able to do so, to retain the dose for a time in the buccal cavity. "In the recent discussion of this subject, no mention was made of one remedy, formerly used for its constitutional effect, but which I have employed for its local action. I refer to the hyposulphite of soda, the use of which was suggested to me by Dr. Brickelmaier, of this city, in an informal conversation some time ago. Since then I have treated eight cases of diphtheria with this remedy, giving hourly doses of ʒj. of a solution of the strength of ʒj. to ℥ij. of water. In two of these cases the pseudo-membranous deposit was very thick and tenacious. In all there was a gradual lessening and disappearance of the membrane from hour to hour. The patients retained the solution in the mouth several minutes before swallowing it. No other local remedies were employed, though the general condition of the patients received proper attention. In one case, which is now under treatment, the deposit is very great and extends downard to a considerable distance. In this case gentle local applications are made by means of a brush. I have not yet had an opportunity to use the remedy when the disease has invaded the larynx, but intend to employ it in the spray-atomizer in the first case of this kind which presents itself. I shall also use the same method when the patient is too young to hold the solution in the mouth before swallowing it. The hyposulphite of soda has also, very probably, a constitutional action, but it is to its use as a topical agent that I now specially wish to direct attention. I disclaim, however, the notion that it will cure in every case, for we all know that some cases will inevitably succumb to the disease despite any and all forms of treatment. As to the manner of making local applications, the gentler and more intelligently the local applications are made the more favorable are the results likely to be; therefore the spray-atomizer is to be preferred in all cases of the buccal and laryngeal forms of the disease. A suitable syringe, carefully used, is to be recommended for the nares and posterior pharynx. As regards the various remedies recommended for use in the spray-atomizer, I have had a greater percentage of recoveries with trypsin than with anything else."

THE EXAGGERATED DANGERS OF COCAINE.

Dr. J. R. Rankin, of Muncy, Pa., writes that he has never seen any alarming effects follow the use of cocaine in his practice, although he has employed it quite extensively. In every case, however, he first assured himself, by careful examination, that there was no heart-disease present, and if there was, he withheld the drug. He first used the remedy in asthma, in August, 1885, inserting from five to ten drops of a ten-per cent. solution into the nostrils, the dose varying according to the severity of the asthmatic paroxysms. The patient was completely relieved by the daily use of the remedy, and suffered from no unpleasant symptoms of any kind. He has had a like experience with another case of a similar nature. These patients used, on an average, from three to four grains daily. He has also employed cocaine, in the form of spray, in laryngitis and catarrhal fever, with most satisfactory results. In a case of gastritis, occurring repeatedly in the same individual, this remedy has been employed with benefit, in doses ranging from one to six grains. The symptoms following the exhibition of these large doses were, reduction of the pulse from 92 to 68, of the respiration from 22 to 15, slight difficulty in speaking, cooling of the skin, copious perspiration, and mental exhilaration. When a dose of six grains was given there was slight confusion of ideas for a few minutes. Dr. Rankin adds that he has used cocaine subcutaneously in a few cases, but likewise without the production of any symptoms of an alarming nature. He does not think that we should be deterred from using so valuable a remedy because it is poisonous in large doses, or because some have acquired the cocaine habit. Such arguments would apply with equal force against the use of opium, belladonna, and a number of most valuable remedial agents.

Progress of Medical Science.

Tuberculosis of the Peritoneum cured by Laparotomy.—Dr. Poten has published the following remarks on this subject: In a recent work on tuberculosis of the female genital organs, Hegar reports several cases of diffuse tuberculosis of the peritoneum which were cured by surgical interference, or, at least, brought to a standstill. Hegar himself has performed laparotomy on two cases of this kind with the best success. Spencer Wells, Neimann, Koenig, and others also have opened the abdomen in tubercular peritonitis, and after removing the transudation have seen cures in such cases. This fact, says Hegar, has been confirmed by too many reliable authorities to be denied; and he adds that cases of such a nature have often been regarded as mistakes in diagnosis, and it was thought that they were a disease *sui generis*, a granular, non-tubercular inflammation of this serous membrane. At the present time, however, the tubercular nature of these cases is hardly doubted. It is, with our present views on tuberculosis and its virus, indeed rather singular that by simply opening the abdomen and removing the ascitic fluid, a peritoneal tuberculosis can be cured, and doubts as to whether the disease in these cases is a genuine tuberculosis or simply a granular inflammation of some other nature, are not unreasonable as long as the tubercular nature of this affection has not been proven with absolute certainty, which can be done by the microscope, and especially by the presence or absence of Koch's bacilli. The reported cases, so far, do not show that these proofs have been brought. On the contrary, judging from Hegar's words, cited above, we would think that in making the diagnosis of this disease the principal reliance was placed on the macroscopical appearance of the peritoneum, which, in this instance, however, would hardly admit of any other explanation. Koenig mentions some cases of tuberculosis of the peritoneum, treated with carbolic acid and iodoform, which the microscope proved to be of a tubercular nature, but even in these no reference was made to the bacilli. The following case, operated on by Dr. Hartwig, is one in which the diagnosis of tuberculosis of the peritoneum has been made with absolute certainty, and is, therefore, of considerable interest: Mrs. R——, twenty-

nine years of age, multipara, last birth one year and seven months ago, was received into hospital December 10, 1885. She had always been healthy, but had swelling of lower extremities while nursing the child. After weaning it, and with the return of her menses, this swelling disappeared, but since May her abdomen commenced to enlarge. Her condition when admitted to the hospital was as follows: She is pale and emaciated; abdomen distended, especially in umbilical region and below, but not tender on pressure. Distinct fluctuation, percussion dull from two inches above umbilicus to symphysis pubis, the same on each side, which change of position does not affect. Prolapse of anterior vaginal wall; uterus mobile and not connected with any abdominal tumor. Ovaries cannot be felt. Thoracic organs normal; temperature—evening, 100.6°; morning, 98.8°. It being impossible to make a positive diagnosis, exploratory laparotomy was resorted to on December 12th. After the thickened peritoneum was incised, a clear, yellowish fluid spirted out through the opening. Slight compression of the abdominal walls was made, and almost a bucketful of ascitic fluid removed. The whole parietal peritoneum was covered with little nodules of a reddish-gray color; intestines, uterus, and ovaries, which were of normal size, were also the seat of these nodules. After all the fluid had been sponged out, and a piece of the peritoneum removed from the edges of the incision, the abdominal wound was closed with silk sutures. Patient made a good recovery, but had slight elevations of evening temperature; dressing and sutures were removed December 23d; the wound was healed by first intention, the abdomen sunken in, and she was free from pain. She left hospital on December 24th. The excised fragment of peritoneum was much thickened, and had lost its normal glossy appearance. Its surface showed numerous miliary and somewhat larger prominences, which in no place were ulcerated. Under the microscope the tubercles had a variety of forms, from the simple granulation nodule to the well-developed giant-cell tubercle with caseated centre; bacilli were found in small numbers almost exclusively within the giant-cells. Mrs. K—— came to the hospital again last summer, on account of a small abscess which had formed in the cicatrix and which healed rapidly. A very short time ago, almost a year after the operation, Dr. Poten saw her again; she had the appearance of a perfectly healthy woman; she had gained in flesh, and was so well that she could do all her housework without the least difficulty. There is no sign of any fluid in the abdominal cavity. Her abdomen, with the exception of a small ventral hernia, has a perfectly normal appearance, and is not tender on pressure. The lungs are entirely normal; she has no cough. Appetite and bowels normal. This case proves clearly that a genuine tuberculosis of the peritoneum has, to say the least, been cured temporarily by a laparotomy. Whether this cure will be permanent, the future will show. This result is so much more remarkable as no application of any disinfecting agent to the diseased peritoneum was made.—*The Pittsburg Medical Review.*

Virchow's Views on Myxœdema.—At a recent meeting of the Medical Society of Berlin, Virchow introduced the subject of myxœdema. He said (*The Lancet*) that although the London Clinical Society had collected details of one hundred and ten cases, and many had been published in France, there were records in Germany of but two or three cases, and these of quite recent date. In his visit to London last October he enjoyed opportunities, especially at St. Thomas' Hospital and the Brown Institution, of becoming familiar with the disease; and his address was largely taken up with the interesting subject of its pathology, as investigated by Professor Horsley. He had been convinced from inspection of Professor Horsley's preparations of the truth of his statement that lymphoid tissue occurs in the thyroid body; but, although accepting the fact that the blood in the thyroid veins is seven per cent. richer in leucocytes than that in the corresponding arteries, he hinted that this difference may be explained by the slower current in the veins, and did not consider the lymphoid tissue to be adequate to entitle the organ to be considered of hæmopoietic nature. As to the nature of a myxœdema, he pointed out that adipose tissue, when atrophying, undergoes mucoid change—a reversion to the fœtal state; but that myxœdema is not a mere atrophic change. On the other hand, it is the outcome of an active process of cell-growth in the cutaneous and subcutaneous connective tissue, with increased bulk, while the superficial layers of the cutis are not involved. It resembles an inflammatory rather than an active process, and he was reminded of the similarity to the condition of phlegmasia alba dolens, or pachydermia. The experimental and chemical researches of Horsley and Haliburton, which prove that extirpation of the thyroid is followed by an increase of mucin in the blood, tissues, and secretions—a condition of "myxœmia"—form a distinct advance in the knowedge of the subject; but Professor Virchow expressed himself with caution upon the theory of the function of the thyroid propounded by Horsley upon these results. Nor does the histology of myxœdema bear out the notion of its being mainly a condition due to retention of mucin; on the contrary, it points to an active irritative process. Professor Virchow next passed to consider the relations between myxœdema and cretinism, and again cited Professor Horsley's experiments on monkeys, which in a few weeks after thyroidectomy passed through a series of stages—neurotic, mucinoid, and atrophic—to death; and where, after exclusion of any nerve lesion, the phenomena were attributed to perverted nutritional changes. He called to mind the ill effects, noted long ago, of the too rapid wasting of the thyroid under treatment of goitre, by iodine—effects attributed by some to iodism, but considered by Virchow himself (*Geschwülste*, i., 114) to be due to the "goitrous cachexia." He discussed the association between goitre and cretinism, and between so-called "congenital rickets" and cretinism, with especial reference to myxœdema, adducing some interesting facts, such as that of two infants, subjects of "congenital rickets:" one presented the characters of myxœdema, and had an abnormally large thyroid; the other was small and atrophied, having no myxœdematous characters, but having extreme atrophy of the thyroid, such as described by Ord in myxœdema. He also referred to Küster's observation upon "cachexia strumipriva," and glanced at the subject of exophthalmic goitre, more by way of contrast than as illustrating any relationship between Graves' disease and myxœdema; and he concluded by admitting that although the part played by the thyroid body in myxœdema was not yet proved, it was a subject worthy of careful study. Professor Ewald, who spoke on the conclusion of Professor Virchow's paper, preferred "cachexia pachydermica" to the term "myxœdema," and suggested that in Horsley's experiments the increase of mucus in the salivary secretion was attributable to injury to the sympathetic during the operation of extirpation of the thyroid. He mentioned that recently Schiff and Herzen had observed spasmodic affections suggestive of cortical irritation to follow extirpation of the thyroid, while Albertoni and Tizzoni had noticed a great diminution in the blood-capacity for oyxgen; and he considered that such varied results proved how far we are from a knowledge of the functions of the thyroid. Drs. Wolff and Bergmann also spoke, their remarks being mainly directed to the effect of partial thyroidectomy in producing atrophy of the remainder of the body—a result which does not obtain in experiments on the healthy organ.

A Case of Obstinate Vomiting of Pregnancy, cured by feeding through the œsophageal sound, is reported by Dr. Brunniche.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, June 4, 1887.

THE TREATMENT OF FIBROID TUMORS OF THE UTERUS BY POWERFUL ELECTRICAL CURRENTS.

WE have already given some notice of the method of treating uterine tumors and other diseases by very strong electrical currents, a method especially identified with Dr. Apostoli, of Paris. In a recent issue of the *Journal of the American Medical Association* Dr. Franklin H. Martin describes the technique in detail, and adds his indorsement of the method. His article limits itself to the consideration of fibroid tumors, hemorrhagic and non-hemorrhagic.

These tumors are treated by currents of electricity from a gravity or Daniell-cell battery, of which about one hundred and fifteen are needed. Other cells, like the zinc-carbon, can be also substituted. The strength of the current used is from a minimum of fifty to a maximum of one thousand milliampères, even the minimum being a stronger current than is ever employed in therapeutics. The effects produced are by the electrolytic or decomposing action, and, to a less extent, by the cataphonic action, of the current.

The two poles have a decidedly different effect. The positive or acid pole has a caustic and styptic power, very useful in hemorrhagic fibroids; but it is a power not obtained except in currents stronger than fifty milliampères. The negative pole has the effect of liquefying instead of hardening and coagulating the tissues.

The electrodes used are simple enough. That for internal use is made of platinum insulated nearly to its tip. The external electrode used by Apostoli is a mass of moist potter's clay moulded upon the abdomen. This is connected with the battery by a plate of soft metal and a conducting-cord. Dr. Martin uses, in place of the clay, a concave disk of soft metal, loosely stretched over the concavity of which is an animal membrane. The space between the membrane and the metal is filled with a warm solution of sodium chloride.

In hemorrhagic fibroids the positive pole is introduced into the uterus, the large electrode placed over the abdomen, and the current is slowly turned on. At first not more than fifty milliampères should be used for about five minutes. Subsequently the strength is increased and the duration lengthened to ten or twelve minutes. The operation has to be repeated several times. By it the hemorrhage is diminished and the tumor lessened in size. In most tumors in which the uterine canal cannot be reached a sharp-pointed electrode of platinum and iridium is introduced directly into the neoplasm via the cervical canal and connected with the negative pole. A current of one hundred and fifty milliampères may here be used.

In a third class of cases the tumor is punctured through the vaginal or abdominal wall. Here an anæsthetic and thorough antiseptic precautions are necessary. In these cases the needle, when introduced by the vagina, is insulated to within one inch of its point, connected with the negative pole, and a current of strength of five hundred to one thousand ampères is used.

The conclusions reached by Dr. Martin are as follows:

1. A means of generating a continuous current of electricity which can be increased from ten to one thousand milliampères in strength is necessary in order to obtain all the benefits of this treatment.

2. Hemorrhages from hemorrhagic fibroid tumors can be cured by the local coagulating effect of the positive pole applied inter-uterine.

3. The inter-uterine electrode, when positive, should be of unattackable metal, conforming as nearly as possible to the size and shape of the uterine canal, and having the vaginal portion insulated.

4. When the cervical canal cannot be entered a negative galvano-puncture should be made into the presenting part of the obstructing mass of the tumor and an artificial canal, which is to take the place of the impenetrable uterine canal in all subsequent treatments, be formed.

5. The intra-uterine electrode should in all cases be negative, unless there is hemorrhage or excessive leucorrhœa, when the positive pole is always required. The same patient may, however, present successive symptoms demanding the use of each pole.

6. The strength of the current should be the strongest possible consistent with the desired therapeutic effect and the endurance of the patient.

7. Cases of intolerance of high doses arrange themselves under the three following heads: 1, Hysteria; 2, enteritis; 3, acute nephritis, perimetritis or parametritis, the most tolerant being the deep uterine and profusely hemorrhagic.

8. The duration of the operation should be from eight to ten minutes, according to the toleration of the patient.

9. The number of operations is necessarily dependent upon and influenced by the result to be accomplished. A severe hemorrhage can be checked in from four to five séances, while a general reduction of the tumor necessitates many operations, varied, of course, according to size and location. In many cases simply a restoration to health and a relief from the prominent and annoying symptons must be accepted as a substitute for an actual cure.

10. The time of commencing the treatment matters but little if the tumor is not rapidly growing and no excessive hemorrhage is present. The operation should be inter-menstrual, if possible, but if hemorrhage is continuous operate during the flow. The séances should occur two or three times a week if compatible with the endurance of the patient, and should be as regular as possible.

11. Extra-uterine puncture should be regarded only as a last resort, but every means of reaching the tumor

through the uterus being impracticable, seek, if possible, to make the operation extra-peritoneal; should this in turn prove equally unadvisable, use as a final alternative the abdominal puncture.

12. Strictest cleanliness and thorough antiseptic precautions are absolutely demanded in operations connected with this treatment.

A MEDICAL HOAX.

A CURIOUS instance of the way in which news sometimes gains in its progress around the world was shown recently in connection with Bergeon's method of treating phthisis. A cable despatch from Philadelphia was printed in the Italian daily press to the effect that a physician of that city had discovered a new and infallible cure for consumption. The wonderful discovery was much discussed in the papers, and many interviews were had by enterprising reporters with prominent medical men on the subject, and all awaited with feverish anxiety the receipt of fuller details by mail. Numerous letters and cablegrams were sent to the Philadelphia physician (we quote *La Riforma Medica*), asking him to send a detailed account of his method, and some sufferers even invited him to come to Italy to relieve them of their ills.

None of the American daily papers of the date of the cablegram contained any notice of the wonderful discovery, and the matter remained a mystery until the receipt of the Philadelphia medical journals. It was then learned that some experiments with Bergeon's method had been made in the hospitals there. One of the assistants at these experiments bore the name of the alleged discoverer of the cure for phthisis, and in some way or other the cable reporter had given to him the honor of originating the method. Many of the poor victims of phthisis have been cruelly disappointed, but a few Italian journals had a sensation, and the cable companies sent some extra despatches.

HEMORRHAGE AND ANTISEPSIS.

ONE of the first rules of antiseptic surgery has always been to carefully arrest all bleeding from the tissues before putting on the final dressing. Of course, the arrest of hemorrhage from large vessels is a matter of necessity, but, if the views recently enunciated by Schede and others are correct, it would seem that a mistake has been made in spending so much time in efforts to repress all oozing from the tissues. It is now claimed that the presence of a clot in the wound, so far from being an accident to be guarded against as retarding the healing of the wound, is actually of benefit and rather favors union. Schede says that the great power of organization of the blood-clot should be utilized, and that the blood should be allowed to enter the wound, thereby filling all its crevices and sinuosities with a plastic material which will be of the greatest utility in promoting union, and will do away with the necessity of compression and drainage.

These views would appear to be based on sound reasoning, for the blood in closed wounds, such as fractures and after tenotomies, is known to be partly absorbed and in part to become organized; and, if perfect antisepsis is maintained, the clot which is formed from effused blood in open wounds should behave in precisely the same way. Of course, the most perfect antisepsis must be obtained, otherwise the blood will be a source of additional danger. But the most perfect antisepsis must be maintained in any case if success in the operation is desired.

A case illustrative of this innocuity of the effused blood is related by Dr. G. Turazza in the *Gazzetta degli Ospitali* of April 13, 1887. A man received a stab wound in the back extending about five inches through the muscles parallel to the thoracic wall. The hemorrhage was very profuse, but it was impossible to find the bleeding vessels. The wound was washed out repeatedly with a four per cent. carbolic acid solution, and then, without any pains being taken to arrest the hemorrhage, the edges were approximated by sutures and an antiseptic dressing was applied. The following morning the dressings were found saturated with blood and were changed. On the fourth day the sutures were removed, and on the eighth day there was a firm cicatrix, the wound having closed by first intention.

Some of the advantages of this method are that much time is saved, since no delay is occasioned by waiting for the oozing to be arrested, and, in most cases, the necessity of drainage-tubes is done away with. At the last French Surgical Congress this question of drainage was thoroughly discussed, and most of the speakers agreed that, when antisepsis was perfect, it was better to leave out the drainage-tubes, and ignore the presence of effused blood. When, however, the operator was not sure that perfect antisepsis could be maintained, they were all of the opinion that drainage should be provided for, since the presence of decomposing blood would, of course, render the condition of affairs only so much the worse.

A PSEUDO-MEDICAL CHARITY.

AGAINST the protests of the profession, the Presbyterian Hospital has put up a dispensary building for out-patients in the midst of one of the wealthiest sections of the city. Such a building in such a place is utterly uncalled for.

TEMPERANCE IN KANSAS.

AN esteemed correspondent, living in Neosho County, Kansas, takes exception to some remarks of THE MEDICAL RECORD, under date of February 12th, concerning the practical working of the prohibition law in that State. He says that the statements of the Osage City *Free Press*, from which we quoted, contained some truth and a great deal of error. The practical results of the old law were not what its advocates had hoped they would be. For this reason there was a tacit agreement among the Prohibitionists to take no notice of any but the most flagrant violation of the law until the Legislature met, when it was expected that a better one would be passed. The new law is now in force, and it would be very difficult, he says, for one to obtain liquor from the druggists for any purpose whatever.

Concerning the practical results of the present law, our correspondent writes: "I can point out a dozen men who formerly spent all their earnings for liquor, while their wives and children went barefoot and hungry.

Now their wives are well dressed, their children are properly clad and in school. Merchants, grocers, doctors, and all say that collections are better than formerly. But, above all, the boys, the future hope of the country, are not exposed to the temptations they formerly were. Please pause and think of it for one moment, and of all it means to fathers, mothers, sisters, wives, and children in the future.

"I could go on indefinitely, and tell you how the law prohibits, and how it has driven out of the State the saloon-keepers, the gamblers, and all that class of men. But it is entirely unnecessary. The whole thing narrows itself down to the question, Does prohibition tend to elevate or depress mankind? If the former, then it is right, and should have the support of all the foremost men of our nation, as well as of all others."

We are glad to learn that good has resulted from the enforcement of this law in some part of the State, for information which we have received from other places is by no means of the same tenor. A medical gentleman, living in one of the larger cities of Kansas, has kindly favored us with a report of his observations of the workings of the law in the cities. "Before the new law was passed," he writes, "each drug-store was practically a liquor-establishment. In most cases the liquor sold was drank off the premises, but in very many instances it was consumed on the spot behind some screen. There is none of that now. But here, as in many other towns in Kansas, whiskey is being sold openly at some saloons behind the bar. The authorities are moving, however, and will probably suppress the sales and rigidly enforce the law as they have done in Leavenworth. The result will be, that men will use liquor all the more freely in their own homes.

"In my opinion the law is, and will prove to be, a curse to Kansas. The law is not reformatory, but prohibitory; and the more rigidly it is enforced, the more determined will men be to obtain their liquor and to have it on hand in their own homes. The action of the law is, in my opinion, more degrading to the morals, and leads to more craft and subterfuge and weakening of a man's sense of honor than would free liquor even. There is certainly no appreciable lessening in drunkenness so far, and no apparent gain in prosperity. This law is, furthermore, only the entering wedge for the passage of Sunday laws of such stringency as to recall the old blue laws of Connecticut. After a time the inevitable reaction will come, and the devil will have greater riot than ever."

The correspondent whom we have just quoted is, by principle and practice, a temperance man in the proper acceptation of the term, and, in common with most medical men, is an earnest advocate of any lawful measures which will have the effect of diminishing intemperance; but, like many other enemies of intemperance, he denies the efficacy of prohibitory laws in the attainment of this object.

We have given prominence to this subject—which, however, we do not think is by any means without the province of a medical journal to discuss—because the first correspondent was "pained that THE MEDICAL RECORD should give an opinion without hearing both sides of the question." The only opinion given was that prohibition does not prohibit. THE MEDICAL RECORD has no quarrel with the Porhibitionists; on the contrary, it wishes that their efforts could ever be crowned with success, but it believes in the exercise of temperance in all things, even in the endeavors made to repress intemperance.

News of the Week.

MAINE MEDICAL ASSOCIATION.—The thirty-fifth annual meeting will be held in the Common Council Chamber, City Building, Portland, Me., Tuesday, Wednesday, and Thursday, June, 14, 15, and 16, 1887.

THEATRE-PARTY AND SUPPER TO AMERICAN LARYNGOLOGICAL CONGRESS.—Dr. George M. Lefferts gave a theatre-party and a supper at Delmonico's, on Thursday evening, May 29th, to the American Laryngological Congress. The party occupied private boxes at the Casino, and after the performance repaired to Delmonico's. The affair was a most enjoyable one throughout. The toasts of the evening were responded to in turn by Drs. A. Jacobi, George F. Shrady, D. Bryson Delavan, of New York, and Dr. S. W. Langmaid, of Boston.

GANT'S SURGERY.—By a typographical error in the review of Gant's Surgery, in the THE MEDICAL RECORD of April 16th, the name was spelled "Galt."

THE OHIO STATE MEDICAL SOCIETY holds its forty-second annual meeting at Toledo, O., on June 15, 16, and 17, 1887.

DEATH OF PROFESSOR VULPIAN.—Another distinguished French physician is gone in the person of Professor Edmond Vulpian, who died on May 18th, in the sixty first year of his age. Professor Vulpian's name was made familiar to the medical world by his contributions to nervous diseases and to the physiology of the nervous system.

DR. THOMAS F. ROCHESTER, of Buffalo, N. Y., Professor of Medicine in the University of Buffalo, died on May 24th. Dr. Rochester was well known throughout this State, and was at one time president of the State Society.

THE IOWA STATE MEDICAL SOCIETY held its annual meeting at Sioux City on May 18, 1887.

A NEW MEDICAL COLLEGE is to be started in Iowa. Its president, according to the Iowa *State Medical Reporter*, is also president of the Iowa Medical Liberty League, an organization whose purpose is to resist the medical laws.

THREE CASES OF SMALL-POX were discovered in different parts of the city on Tuesday.

THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY held its Annual Commencement on May 31st. Degrees were conferred upon a class of seven. Rev. Henry J. Van Dyke delivered the address.

ICHTHYOL has proved a disappointing and untrustworthy remedy in the experience of Dr. George T. Jackson, who has used it in twenty-two cases of skin disease.

CHOLERA IN CUBA.—Six cases of cholera have been reported as occurring near Havana.

The Massachusetts Medical Society holds its one hundred and sixth annual meeting at Boston on June 7th and 8th.

Should Physicians Furnish their own Medicines?—We continue to receive numbers of letters from physicians, all having the same tenor—viz., that it would be better for both physician and patient if less work were thrown on the druggist. Dr. Daniel D. B. Beaver, of Reading, Pa., in particular, sends us an able and logical argument in this line. There can be no doubt that the sentiment of the profession decidedly favors the view that physicians should furnish their patients with medicines to a greater extent than is now the case. However, this can be overdone; the doctor cannot be a good doctor and a first-class druggist. The country practitioner and the homœopath already furnish their medicines, and the practice is not a novel one.

Take "The Medical Record."—"We sadly want a medical journal which is innocent of sycophantic obsequiousness, one which is fearless and true, and animated by love for the profession, and not for the filthy lucre which it brings."—*Hospital Gazette.*

Organization of the Medical Department of the House of Refuge.—The Board of Managers of this institution have appointed a staff of consulting physicians, consisting of Dr. Stephen Smith, President; Drs. A. A. Davis, John H. Ripley, and J. B. White; and Dr. George A. Spalding, Secretary. This medical board will soon hold an examination of candidates for the position of resident physician. The latter is to receive a salary, to reside in the institution, and to hold his position at the pleasure of the board.

A Case of Gaseous Gangrene affecting the subcutaneous cellular tissue was reported recently by Dr. H. C. Dalton, before the St. Louis Medical Society. A similar case was observed in Bellevue Hospital in April, 1878, and reported by Dr. E. G. Janeway, to the Obstetrical Society, if we remember correctly. The case occurred in a woman who had aborted at three and a half months.

Ante-mortem Earth Treatment.—A distinguished Philadelphia Surgeon advocates the systematic use of earth as a topical application to wounds. This is a very old treatment, but heretofore surgeons have waited until after the patient was dead before making topical application of earth.

Christian Science.—We are in receipt of a copy of a vigorous and logical sermon preached by the Rev. Dr. David J. Burrell, of Dubuque, Ia., in which the *rationale* and the absurdities of "Christian science" are very clearly unfolded.

The Michigan State Medical Society held its annual meeting at Lansing, Mich., May 12th and 13th. About two hundred members were present. A large number of papers were read in the different sections. The following are the officers elected: Theo. A. McGraw, M.D., Detroit, President; C. V. Tyler, M.D., Bay City, 1st Vice-President; W. J. Herdman, M.D., Ann Arbor, 2d Vice-President; G. L. Rose, M.D., Decatur, 3d Vice-President; F. J. Grone, M.D., Big Rapids, 4th Vice-President; George Duffield, M.D., Detroit, Secretary; H. B. Hemenway, M.D., Kalamazoo, Treasurer.

Training-school for Male Nurses.—It is stated that Mr. D. O. Mills has given $80,000 for a building to be erected on the grounds of Bellevue Hospital to be used mainly as a training-school for male nurses. The Wood Museum will occupy the top story. The building will be erected in the rear of the college.

Hospital Scandal in Vienna.—At a recent sitting of the Reichsrath, Herr Pernerstorfer called attention to the management of the Vienna Allgemeines Krakenhaus. The charges which were made were that the food is unwholesome and scanty. At times the patients are kept for days without any food at all. In the whole establishment there is only one bath, and the nurses, of whom 219 are women and 17 men, extort money from the wretched patients and ill-treat those who cannot pay.

Richardson's Syrup of Superphosphate of Iron and Oxygen is made by the following formula: ℞. Syr. superphosphate of iron, sol. hydrogen peroxide (ten per cent.); pure glycerin, āā ℥ j. M. Sig.: ʒ j. to ʒ ij. t.i.d. in ℥ iij. of water.

The Apostoli Treatment of Fibroids by strong galvanic currents seems to be growing in favor, and American gynecologists will do well to pay attention to this matter. Mr. William W. Webb, on the advice of Sir Spencer Wells, went to Paris and studied the matter for several months, being under Apostoli's directions. He now writes to the *British Medical Journal:* "The upshot of all this is that I am perfectly satisfied much good has been done; many women have been gradually, and without suffering, set up in health, who would, under ordinary circumstances, have been condemned to the risks of some cutting operation. The evidence that, by the treatment of Dr. Apostoli, all the symptoms caused by these tumors can be relieved; that the tumors can be reduced in size; that patients can be made to regain their usual health, powers, and enjoyment of life, is so clear, indisputable, and convincing, that in spite of all doubt, prejudice, and insinuation, it must be accepted. Or, since it stands on no better foundation, we may make up our minds to renounce the greater part of gynecological science, reject the testimony of our senses, nullify ourselves in the fool's paradise of fatuous incredulity, and adopt the negation of a creed in the words of the old saying, 'All medical facts are lies.' Seeing what I have seen, and knowing what I know of the galvano-caustic treatment of uterine fibroids and hypertrophies, I should deem myself wanting in philosophic self-denial and Christian charity if, finding myself face to face with a woman suffering from such disease, I were to menace her with an operation of excision, either of her tumor or appendages. There is an alternative to propose, which is not, like myomotomy, capped with a chance of two to one against success (latest table compiled in Paris, 1886), and which is not mutilating or sterilizing like oöphorectomy. Even if the tumor be not eradicated, a woman enduring symptoms calling for operative interference would think herself happy, after a little patience and no more pain than is the accompaniment of her disease, to find that she had changed for the same condition of ease and freedom she might have with a pregnancy of a few months."

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, April 11, 1887.

A. Jacobi, M.D., Chairman, *pro tem.*

Dr. Daniel Lewis presented an old woman from whom he had

REMOVED A BREAST UNDER COCAINE,

given according to Dr. Corning's method (see p. 634).

Dr. Lewis also reported a case of

PAGET'S DISEASE OF THE NIPPLE,

and exhibited the specimen. Cases of the disease now known in surgical literature as "Paget's disease" were sufficiently infrequent to render their description interesting and instructive.

The following history was from the records of the New York Skin and Cancer Hospital, the patient having applied for treatment, March 1, 1887. She was forty-five years of age, married, and the mother of several children (which she nursed), and had never suffered from any of the diseases of the nipple or breast incident to lactation. Thirteen months ago, without any apparent cause, the right nipple became the seat of a dry eczema, the surface and the areola becoming red and roughened, finely granular, and attended with a tingling, itching, and burning sensation. In a few weeks the nipple had become considerably larger than the other, and all these symptoms had continued with increasing severity. Darting pains radiated from the nipple toward the axilla, and a few weeks before admission enlargement of the axillary glands was first discovered. On admission the entire nipple and areola were found indurated and tender—the infiltration extending downward and outward to the diseased lymphatics, but the mammary gland in other portions was apparently free from disease. The nipple was elevated an inch above the surface of the breast, and about one and a half inch in diameter at its base.

THERE WAS NO FAMILY HISTORY OF CANCER, AND THE PATIENT'S GENERAL CONDITION WAS GOOD.

The ordinary treatment for eczema had been employed without benefit. Here, then, were presented all the features described by Paget in vol. x., p. 87, of "St. Bartholomew's Hospital Reports" as belonging to the cases in which the eruption was a *dry* one, but several of his were moist, some discharging even copiously, the fluid being clear, yellowish, and viscid. Mr. Paget's cases were fifteen in number, and their ages ranged from forty to sixty years.

Mr. H. T. Butlin made a careful microscopical study of some of them, in which he found the ducts widely dilated and frequently filled with masses of squamous epithelium, while the connective tissue was infiltrated with small cells. A later examination revealed cell-nests in the thickened portions of the nipple and areola, and much greater enlargement of the acini and ducts, the contents of which had made their way into the surrounding tissues. In this stage

THE DISEASE HAD BECOME TRUE CARCINOMA.

Mr. Thin has pronounced these cases epithelioma of the lacteal ducts, but S. W. Gross and many others hold the view of Mr. Paget, that the disease is primarily a simple eczema of the nipple, and from the long-continued irritation produces cancer, just as ichthyosis of the tongue has been shown to produce epithelioma of that organ.

Mr. George Lawson reported a case of long-standing eczema of the nipple to the London Clinical Society (*Lancet*, June 4, 1881), in which he removed the breast, throughout which the microscope revealed cancer-elements. He advocated the excision of the breast in any case where an eczema of the nipple resists all treatment.

Instances of cure of this disease have been reported by Gross and Bush, which simply prove its benign nature in the beginning of its history, or, as Hutchinson terms it, in the "pre-cancerous stage" of a form of carcinoma whose malignancy in the later stages is too evident to be mistaken by anybody.

Removal of the entire breast and axillary glands (whether diseased or not) was advised in Dr. Lewis' case, and at the present writing the patient was well.

Dr. C. A. Powers then read a paper (see p. 623)

ON MENINGEAL HEMORRHAGE—ITS TREATMENT BY TREPHINING AND COUNTER-OPENING FOR DRAINAGE.

Dr. Robert T. Morris saw no reason why, in cases of meningeal hemorrhage and also in some cases of apoplexy, an operation should not be performed for the purpose of controlling the hemorrhage and removing the clots.

He believed that catgut was the only means of drainage that should be used, as there was no necessity for its removal, and thereby disturbance of the brain was avoided.

As to whether or not the dura mater should be closed was a difficult question to decide, for if the wound be left open there was danger of hernia cerebri, and if closed there was danger of pressure from pent-up serum and detritus. He then mentioned the importance of antiseptic precautions under such circumstances.

Dr. Frank Ferguson, on invitation, spoke, and said he had seen many post-mortem cases in which he could have wished for surgical interference. He thought that perhaps sufficient stress had not been laid on the fact that hemorrhage outside of the dura makes up only a small percentage of the cases of meningeal hemorrhage. In the vast majority of cases, with fracture of the skull, the hemorrhage is in the pia mater or upon its very surface, and does not seem to be at all connected with the dura mater. Besides, it is difficult to locate the source of the hemorrhage.

Nevertheless, cases of extra-dural hemorrhage occurred, with the blood between the dura mater and the bone, and caused the death of the patients, not by laceration or destruction of brain-substance, but by pressure upon the brain.

Dr. Ferguson suggested

AUSCULTATORY PERCUSSION AS A MEANS FOR DIAGNOSTICATING FRACTURE OF THE SKULL AND LOCATING THE CLOT.

He had been able to locate a clot 3 in. by 1 in. by this means, and if relief could be afforded in such cases by surgery it would be a very great advance. He saw no good reason why these patients should not be operated upon; for the vast majority of them die under present management.

With regard to the frequency of middle meningeal hemorrhage, he believed that hemorrhage occurred more frequently at the base or in the middle fossa.

There was one point which might affect an operative procedure, and that was difficulty in removing the clot. He had found it very difficult at times to remove it at post-mortem, and certainly the difficulty would be increased when compelled to work through a small opening in the skull. He thought that there would not be any special danger on account of the continuation of the hemorrhage, because the vessel would almost certainly be plugged by a clot.

Dr. Amidon mentioned the fact that

DR. DETMOLD, NEARLY FORTY YEARS AGO,

opened an abscess contained in one of the lateral cerebral ventricles, and saved the life of the patient for several days, and that operation was done without anæsthesia and before the days of cerebral localization. The

greatest need in reference to cerebral surgery was more accuracy in cerebral localization. The basal symptoms, especially in extra-dural hemorrhage, were very embarrassing; but their existence did not necessarily constitute a contraindication to operative measures. He especially commended the counter-opening and through drainage.

Dr. Jacobi said, concerning Dr. Detmold's operation, that after the case was published it was referred to in the first volume of Virchow's "Archives" as "just such a swindling affair as we should expect from America," and in the same volume could be found Detmold's letter in reply. He would recall Schneider's last case, in which part of the brain was removed, and also a portion of the dura.

Dr. M. Josiah Roberts remarked that surgical trephining was not confined to modern times; but there was evidence that it was a prehistoric operation.

Dr. Powers said, regarding drainage, that he had used catgut extensively in soft parts other than the brain, and that in many cases it had so swollen as to occlude the opening rather than drain the cavity. He felt sure that in the cranial cavity, where the question of life or death of the patient was so imminent, the surgeon could not afford to run any risk, such as must be taken in the use of catgut for drainage. In the cranium, if the discharge be obstructed, such changes will take place as favor the rapid development of meningeal inflammation, which is much more formidable than inflammation occurring elsewhere. He should also be unwilling to use horsehair, although he regarded it as far preferable to catgut.

Dr. Robert F. Weir, Chairman.

Dr. Robert T. Morris then read a paper on

THE REASONS FOR TAIT'S SUCCESS IN AVOIDING SEPTIC ACCIDENTS.

The central point in the paper was in the statements that the same number of microbes, when introduced into the knee-joint, would produce disastrous inflammation, but when introduced into the peritoneal cavity might not produce unpleasant consequences because of the extensive absorbing surface and the ability of the emunctories to carry them away.

If decided cleanliness, therefore, be observed, the risk of introducing microbes into the peritoneal cavity was small, and the giving, as Mr. Tait does, a cathartic on the fourth or fifth day acts like an antiseptic and carries the septic material out of the system through the emunctories whither it has found its way. In other words, by the bowels was removed the septic infection which, if allowed to remain, would develop into serious, if not fatal, septicæmia.

Dr. Polk regarded the main drift of the paper as very interesting, especially to those who had practised the method with such results as to lead them to commend it highly.

But there was another point which to him had been equally interesting. Take the case of a woman who began to show signs of septicæmia, and she was purged, but the purgation was not sufficient to arrest the disease and the patient died. The autopsy revealed a focus of infection in one of the tubes. If the woman had had

PROPER DRAINAGE IN ADDITION TO PURGATION,

it was possible that she might have been saved. He would say that purgation was not to be substituted for drainage at all. It was to be employed in the milder cases of septic infection, whether drainage was effected or not; but it was not to come in competition with drainage.

The plan of treatment by purgation was an old one, and the results obtained in the old times were not satisfactory. It proved to be a failure, as was shown by the success which attended the plan of treatment laid down by Dr. Alonzo Clark. But now, when the abdominal cavity was opened and washed out, we had the ideal treatment of peritonitis.

Mr. Tait does not permit his patients to have opium, even though they have considerable pain, and Dr. Polk thought it was a very good point. But where there was peritonitis, he had not been able to rid himself of the opinion that opium was an excellent remedy; indeed, better than any other remedy at our disposal.

Dr. Wylie said that the subject was one in which he had been very much interested. So far as he knew, Mr. Tait was the first to revive the idea. But Dr. Wylie had been studying and practising from a somewhat different stand-point than had Mr. Tait. Mr. Tait had succeeded because he had used purgatives early. Dr. Wylie was satisfied that if they were given early the success would be very great; whereas, if delayed, they would do no good. His own view was that the symptoms present at the time when the purgatives were administered, such as eructations, nausea, etc., were due to *obstruction of the bowels*, and that relief followed because of the removal of the obstruction rather than because septic germs were carried off. He believed that Dr. Morris was wrong in assuming that

SEPTIC GERMS ENTER THE PERITONEAL CAVITY,

because Mr. Tait operates so rapidly and through so small an opening, which was filled by his fingers, that literally nothing got into the cavity. He also thought that Mr. Tait's success had increased since he used the drainage-tube, the object of the tube being really to keep the peritoneal cavity empty and thus promote the glazing over of the bleeding-points on the peritoneal surface, which would not take place if there was serum there. Besides, the drainage-tube was so serviceable for detecting hemorrhage.

Dr. Mundé said it seemed to him that the reason of Mr. Tait's success lay in the rapidity with which he operated, the extreme cleanliness which he observed, and opening the cavity with a small opening just sufficient to admit two fingers. Under such dexterous operating he was unable to see how any germs could get into the peritoneal cavity. Perhaps his success in other fields was not so much greater than that of others; but in his own operation he had surpassed by far all others, and Dr. Mundé could not help believing that Mr. Tait was so successful chiefly because he did so little injury in the peritoneal cavity.

He regarded purgatives as very good, given at the proper time, but he did not believe that they could be called an antiseptic measure. He did not believe that

GERMS ARE CARRIED OFF IN THIS MANNER.

He always felt, when he had put in a drainage-tube, that he had added another element of danger, although in proper cases it was a necessary and inevitable evil, and in cases of doubt he would introduce a drainage-tube.

Dr. Weir thought that the real question was to explain the success of Mr. Tait in *preventing the extension of septic infection*. He also, in common with others, believed that dexterity had much to do with the success of Mr. Tait; but, at the same time, it must not be overlooked that he was cleanly to the last degree, that he was practising what later observations had shown to be very good *antiseptic* treatment, and that he himself guards his sponges very closely. But when Dr. Weir saw him pour, from a pitcher, water into the abdominal cavity, he was unable to explain how germs were excluded. But it was doubtless true that not every germ that entered a wound created a disturbance; that

AN APPRECIABLE QUANTITY OF GERMS IS REQUIRED TO PRODUCE SUPPURATIVE ACTION.

These facts enabled him to get at something of the reasons of Mr. Tait's success. Another point was that he was not only dexterous in operating, but he was also wonderfully expert in meeting emergencies.

Dr. Wylie said that, looking at the question from his own stand-point, he thought that Mr. Tait and Mr. Bantock used antiseptics almost as completely as either he or anyone present did. Above all, Mr. Tait succeeded because he had a large brain. But with that he took the greatest pains not only to keep his house clean, but the body and bed-linen of his nurses and patients clean, and his beds could be said to be almost literally a Lister dressing. There was asepsis, if not antisepsis, and practically they both "got there just the same."

Dr. Biggs thought that Dr. Morris was wrong in his premises in the assumption that Mr. Tait has to deal with septic infection under the circumstances mentioned. He believed that all workers in bacteriology appreciated the fact that in the atmosphere of most rooms there were germs, but that they were of little danger, and that even in hospitals there was but little danger of germs entering the operation-wound when proper precautions were exercised. Watson Cheyne had shown that certainly the production of disease was in direct proportion to the number of germs introduced. But the absorbing power of the peritoneum was so great, and the surface was so large, that the number of germs that affected it was comparatively small. And the number of germs introduced by pouring in water, even though it be not sterilized, was very inconsiderable indeed. Boiling rendered water perfectly aseptic, and if continued long enough would kill all the spores. A comparatively large quantity of germs was required to produce even such a disease as erysipelas. As regards

THE ACTION OF PURGATIVES AS ANTISEPTICS,

it seemed to him questionable whether purgation would carry off germs.

Dr. J. E. Weeks expressed the belief that Mr. Tait's methods were essentially antiseptic. In water the number of germs was very slight, and, according to his observations, a large number of micro-organisms were required to begin the suppurative process. He believed that but very little of the good effect produced by purgatives could be ascribed to their power to carry off germs.

Dr. Morris, in closing the discussion, said several had remarked that purgatives could not carry off germs, and that they simply acted upon the emunctories. That was the point which he wished to make, namely, that bacteria were eliminated by the emunctories, and that these were stimulated by purgatives.

True it was that a certain number of bacteria were required to produce suppuration, etc., and the peritoneum could effectually rid itself of a large number, but that they were of importance could be made apparent by the fact that the same number when put into the knee-joint would probably kill the patient or necessitate amputation.

The Section then adjourned.

Digitaline in France and in Germany.—Physically and chemically (1) all the French crystallized digitalines are nearly identical; (2) Homolle and Quévenne's digitaline and the Codex amorphous digitaline are very nearly identical with the German *digitoxine;* (3) German digitalines are quite different from the French. Toxically (1) the crystallized digitalines—either Nativelle's, Homolle and Quévenne's, or Duquesnel's—are substantially alike, from two to three centigrammes being sufficient to kill a dog weighing twelve to fifteen kilogrammes; (2) the amorphous French digitalines—Codex chloroformic, Homolle and Quévenne's, etc.—have very sensibly the same toxic power; (3) the product sold in Germany under the name of digitoxine, and considered there the most active principle in digitalis, possesses about the same toxicity as crystallized digitalines. Two things at least seem clear from M. Lafon's investigations, namely, that German digitoxine and French digitaline are substantially identical, and that German digitaline is a product quite different from either.—*Therapeutic Gazette.*

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, held in Washington, D. C., May 11, 12, 13, *and* 14, 1887.

(Concluded from page 620.)

Friday, May 13th—Third Day—Morning Session.

OFFICERS FOR ENSUING YEAR.

President—Dr. D. Hayes Agnew, of Philadelphia.

Vice-Presidents—Dr. N. Senn, of Milwaukee; and Dr. F. S. Dennis, of New York.

Secretary—Dr. Jacob R. Weist, of Richmond, Ind.

Treasurer—Dr. Phineas S. Conner, of Cincinnati, O.

Recorder—Dr. J. Ewing Mears, of Philadelphia, Pa.

Council—Drs. J. S. Billings, L. McLane Tiffany, Moses Gunn, and R. A. Kinloch.

Chairman of Committee of Arrangements—Dr. John S. Billings, of Washington.

The following were elected to membership: Drs. Charles B. Porter and Morris H. Richardson, of Boston, Mass.; and Dr. William M. Masten, of Mobile, Ala.

The next meeting was to be held at the call of the President.

Dr. L. McLane Tiffany, of Baltimore, read a paper on

SURGICAL DISEASES OF THE WHITE AND COLORED RACES COMPARED.

The paper was based on the record of 4,930 cases, studied during a period of thirty-four months in a general hospital. The percentages of the affections were given in detail. The paper was simply intended as a preliminary communication, and, as a result of a study of the figures obtained, the following suggestions were made:

1. Surgical affections follow different courses in the white and colored races, under identical hygienic surroundings.

2. Surgical injuries and operations are better borne by negroes than by whites.

3. Surgical diseases involving the lymphatic system, especially tubercular, are more fatal and more rapidly fatal in negroes than whites.

4. Congenital deformities are rarer in negroes than in whites.

5. The surgical differences observed in whites and negroes are due to racial peculiarities.

DISCUSSION.

Dr. W. T. Briggs, of Nashville, Tenn., considered negroes very prone to suppuration. Negroes bear operations better than whites, but they do not get well so rapidly. While malformations are less frequent, still they do occur. The rarity of hydrocele in the hospital records may be explained by the fact that negroes do not usually seek advice until the tumor has become so large as to give rise to much inconvenience. Fibroids and fibrocystoma are very common in the negro. Ovarian tumor is rare, although he had seen one case in which the tumor weighed one hundred pounds.

Dr. D. W. Yandell, of Louisville, Ky., agreed with Dr. Briggs in his remarks. He had seen many cases of keloid in the negro, but had not seen a case in the white subject. He had seen but two cases of hydrocele in the negro, and never saw hare-lip in the negro. He had seen but two ovarian tumors in the negro. Epilepsy is exceedingly rare in the negro. I never saw a case of internal hemorrhoids in the negro. Tetanus is exceedingly common, especially in the black race. Stricture of the urethra is exceedingly common among negroes.

Dr. R. A. Kinloch, of Charleston, S. C., thought that in considering this subject a mistake was made in classing all negroes together. He thought that in the pure negro suppuration is less likely to occur than in the white race. As a rule, the pure negro is not strumous. Mulattoes are, as a rule, strumous. The pure negro bears operation well and recovers promptly.

Dr. B. A. Watson, of Jersey City, N. J., read a paper entitled

AN EXPERIMENTAL STUDY OF THE EFFECTS OF PUNCTURE OF THE HEART IN CASES OF CHLOROFORM NARCOSIS.

The investigation of this subject was suggested to him by the following occurrence: On February 20, 1887, he had killed with chloroform a dog. The abdominal and thoracic cavities were opened about four minutes after the heart had ceased to beat. The assistant seized the heart with his thumb and forefinger, and the pulsations at once began, the contractions became full and regular, and continued three minutes. They were again stimulated by a second touch, action continuing two minutes. They were started a third time and continued to beat one-half minute. This observation suggested the possibility of arousing the heart into action even after entire cessation of its movements, by the introduction of a needle into the organ.

The results of sixty experiments on dogs were given in detail. The experiment consisted briefly in producing death by chloroform inhalation, and then within from one to three or four minutes an aspirating needle was introduced into the heart through the chest-wall, the attempt being to reach the right ventricle. In the first fifty cases the chloroform was administered rapidly, and air was excluded as far as was possible. In the last ten the chloroform was administered slowly and with a large proportion of air. The first forty animals had already suffered some severe traumatic injury, while the last twenty were perfectly healthy animals. The punctures made in these sixty experiments were as follows: Right ventricle, 38; left ventricle, 6; right auricle, 6; superior vena cava, 3; inferior vena cava, 2; apex of the heart, 2; and not stated, 1. The resuscitations were as follows: After puncture of the right ventricle, 9; right auricle 1. The first forty experiments gave only four recoveries, while the last twenty gave six. In only one of the sixty cases did the heart fail to respond to puncture, and in this instance the use of the needle was postponed for four minutes after the cessation of the heart's action, and one minute after breathing had stopped.

In chloroform narcosis the heart is found in diastole, and the veins in the lungs are greatly distended with blood. It may therefore, theoretically, be assumed that blood may be advantageously drawn from the right side of the heart. The author was assured that this procedure was practical and advantageous.

The only deaths during these experiments which could be attributed directly to the puncture were those in which the needle penetrated the vena cava. In these cases there was profuse hemorrhage into the thoracic cavity. Punctures made into the auricle are sometimes followed by a flow of blood into the pericardium. Punctures into the ventricle are not attended with any hemorrhage from the interior of the organ, but there may be a few drops of blood from a wounded cardiac vein.

The following conclusions were reached:

First, puncture of the heart, especially of the right ventricle, stimulates muscular contractions, and may be advantageously applied in the treatment of chloroform narcosis.

Secondly, the best results are obtained when abstraction of blood from the cavity of the ventricle is combined with the stimulating effects produced by the entrance of the aspirator-needle.

Thirdly, the puncture of the right ventricle is a safer and more efficient operative procedure than the puncture of the left ventricle.

DISCUSSION.

Dr. N. Dandridge, of Cincinnati, said that we should be careful how we apply the deductions from these experiments to the human being. The conditions under which the experiments were made were different from those under which accidents usually occur in human beings. In the latter case the accident usually occurs after only a small quantity has been taken, and often early in its administration. In the experiments reported puncture was resorted to within one or two minutes after the cessation of the heart's action. In the accidents with chloroform it is not uncommon to have recovery after apparent cessation of the heart's action for a comparatively longer period. A large number of experiments are required to test the relative value of this procedure as compared with artificial respiration, the use of nitrite of amyl, and particularly with the subcutaneous injection of atropia. This latter can always be done quickly, and has a stimulating effect upon the cardiac and respiratory centres.

Dr. L. McLane Tiffany, of Baltimore, remarked that there are two points in which these experiments are open to criticism. It is well known that on dogs chloroform acts in a very uncertain manner. It is not safe to make deductions from the dog to the human being under these circumstances. In the second place, it is not well to make experiments in the laboratory and then advise others to try them on the human subject. The experimenter should test the experiments on the human subject before he recommends the procedure to others.

Dr. R. A. Kinloch, of Charleston, reported a case of chloroform narcosis in which heart-puncture was tried, but without the slightest benefit.

Dr. T. J. Dunott, of Harrisburg, described a case in which the heart was twice punctured with an aspirator-needle and blood drawn from the cavity of the heart. It was a case of dilatation of the heart, with general dropsy, etc. The operation was performed by a homœopathic practitioner under the idea that he was dealing with a case of dropsy of the pericardium. A large quantity of blood was removed, and for a time there was improvement. The symptoms again returned and the operation was repeated, with a fatal result.

Dr. B. A. Watson, of Jersey City, said, with reference to the action of chloroform on the dog, he was well aware of the uncertainty of its action; but this is all against the dog. Where he had attempted to continue the anæsthetic action of chloroform on dogs for two hours, he lost one-half of the animals.

The committee to which was referred the suggestions contained in the President's address reported that in view of the satisfactory manner in which the work of the present meeting had been prepared, it saw no reason for a change, and did not recommend the appointment of a business committee. It recommended the adoption of the second suggestion with reference to the length of the papers. With reference to the abrogation of Article 9 of the Constitution, the committee was in accord with the President, but as this article had been introduced at the express desire of the first President of the Association, it was recommended that it be allowed to remain. The committee recommended the adoption of the suggestion that applications for membership lie over for one year.

Adjourned.

AFTERNOON SESSION.

Dr. T. J. Dunott, of Harrisburg, read a paper on

HYPERTROPHY OF THE TONGUE, OTHERWISE KNOWN AS LINGUA VITULI, LINGUA PROPENDULÆ, AND MACROGLOSSA.

This affection of the tongue, although rare, is mentioned by nearly all surgeons of large experience. The case described by the speaker was that of a girl, twelve years of age, admitted to the Harrisburg Hospital, January 6, 1886. The tongue protruded from the mouth a distance of three and five-eighths inches. The lips were greatly distended and the angles of the mouth not far removed from the external opening of the auditory canal.

The greatest width of the tongue was four and three-quarters inches, and the greatest circumference nine and three-quarters inches. The prolapse of the tongue was only of two months' duration, and had begun without apparent cause. The measurements taken one week after admission showed a decided increase in the size of the tongue. The tongue was removed, February 19th. After providing against hemorrhage the organ was removed with scalpel and scissors, the section being so made as to secure a conical stump. All the dense fibro-mass was taken away, the weight of the removed portion being over ten ounces. By January 31st the stump was entirely healed. There was no difficulty in keeping the mouth closed. When heard from, March 23d, she could eat and drink without difficulty and was gaining flesh rapidly. The paper was concluded with an account of the various operations which had been practised for the removal of the tongue.

Dr. L. McLane Tiffany, of Baltimore, reported the case of a negro girl, five years of age, who had suffered with hypertrophy of the tongue dating from birth. The tongue was removed with the Paquelin cautery. Within a week the patient was eating meat, and left the hospital ten days after operation. At this time there was a healthy, granulating surface.

Dr. J. Ford Thompson, of Washington, presented the history of

TWO CASES OF VAGINAL HYSTERECTOMY.

Case I.—Mrs. A. E——, forty-five years of age, white, was seen in April, 1885, suffering with malignant disease of the uterus. There was great destruction of the cervix, the ulceration extending above the internal os. On consultation it was decided to avoid hysterectomy if possible, but to limit the operation to amputation of the cervix, with scraping, etc. During the operation the peritoneal cavity was opened. It was then decided to extirpate the uterus. The womb was separated from the bladder in front. A ligature was then placed around each broad ligament and tied. The uterus was then split in two. Each half was then brought down, the broad ligaments tied above the temporary ligatures, and the uterus removed. After thorough cleansing the vagina was lightly packed with iodoform gauze. At the end of the operation the patient was very weak, and notwithstanding all efforts died in the course of twenty-four hours.

Case II.—Mrs. H——, white, fifty-five years of age, came under observation, with cancer of the cervix, in January, 1887. The posterior lip of the cervix was almost entirely destroyed and the disease had encroached upon the posterior cul-de-sac. The cervical canal was involved at least as high as the internal os. The operation was performed, February 28, 1887, antiseptic precautions being adopted throughout. The dissection was begun at the posterior part and carried around the cervix. A silk ligature was passed with a long, curved needle through the lateral vaginal vault of either side and tied. The enclosed portion was then cut from the uterus. These ligatures presumably enclosed the uterine arteries and the lower part of the broad ligament. The uterus was then separated from the bladder in front and a loop of silk was attached to the peritoneum. The posterior cul-de-sac was treated in the same way. The uterus was then tilted through the opening, and the broad ligaments transfixed and tied. There was no loss of blood. The peritoneal flaps were then brought together with two catgut sutures, and a drainage-tube introduced into each angle of the wound. The vagina was packed with iodoform gauze. The patient recovered without any unpleasant symptoms.

Reference was then made to the history of the operation and the various methods of performing it were described.

DISCUSSION.

Dr. T. R. Varrick, of Jersey City, said that it is a question to be yet determined whether such operations as this are likely to mitigate suffering or prolong life beyond the average duration of the disease if left to take its course without interference. Any operation or method of treatment whose record does not show a prolongation of life beyond the utmost limit of the duration of the disease if left to itself is useless and should be avoided.

Dr. T. F. Prewitt thoroughly agreed with the author that extirpation of the uterus is a justifiable operation, and was almost prepared to go further and say that on the earliest appearance of epithelioma of the cervix the whole organ should be extirpated. He believed that ultimately this will be the course adopted.

Dr. E. H. Gregory, of St. Louis, said that he should no more think of removing the entire uterus for epithelioma of the cervix than he should think of removing the whole lip for limited epithelioma of that part. He thought that the surgery of the lips and the surgery of the jaws is applicable to the uterus.

Dr. T. G. Richardson, of New Orleans, presented the history of a case of

ANEURISM OF THE LEFT SUBCLAVIAN ARTERY FOR THE CURE OF WHICH THREE METHODS OF TREATMENT WERE EMPLOYED—DEATH.

The patient, a healthy, muscular Irish laborer, came under observation, October 19, 1885. Aneurism of the left subclavian artery was diagnosed. The patient had suffered with syphilis and constitutional measures were first tried. Iodide of potassium in fifteen or twenty-grain doses was given three times a day. At the end of a week, no perceptible effect being observed, it was discontinued. Direct pressure was next tried; an elastic band with a compress over the vessel was secured to a belt around the waist. This was continued a month, and although it slightly retarded the growth of the swelling it had had no decided result. The third method, the introduction of surgical pins, was next resorted to. Nineteen of these, measuring an inch and a half in length, were passed through the anterior wall of the tumor at different places. The aneurism was still growing rapidly, and all the pins that could be reached were withdrawn. Some of them had disappeared on account of the swelling which had taken place. An attempt was then made to ligate the axillary artery, but in spite of the utmost care the lower portion of the aneurism was ruptured in the progress of the operation. The wound was at once packed with lint dipped in Monsel's solution. The hemorrhage having been stopped, half a drachm of a five per cent. solution of perchloride of iron was injected into the centre of the tumor. At the end of twenty-four hours, no coagulation having taken place, a second injection of twice the strength was employed. The next morning there was an exhausting hemorrhage, ending fatally in a few hours.

Dr. T. G. Richardson, of New Orleans, related a case of

FEMORAL ANEURISM CURED BY ELEVATION AND FLEXION OF THE LIMB.

The patient, an Italian, aged fifty-five, was admitted to the hospital, December 11, 1886, with a large aneurism of the femoral artery, four inches below the femoral arch. While the case was being studied the limb was flexed at a right angle at the hip and knee and suspended on a Smith's anterior splint. The next day the pulsation was greatly reduced and the patient was quite comfortable. The treatment was continued, and at the end of the third day the tumor was solid. The limb was kept in this position for ten days or two weeks. The patient was discharged cured one week later. The speaker called attention to the fact that there was no direct pressure upon the tumor and that the result was due entirely to flexion and suspension of the limb.

Dr. David Prince, of Jacksonville, Ill., read a paper entitled

WOUNDS—THEIR ASEPTIC AND ANTISEPTIC TREATMENT.

After referring in general terms to the methods in use for the prevention of contamination of wounds, the speaker described an operating-room which he had devised, the object of which was to prevent the entrance of infecting principles. All the air entering this room is filtered through successive layers of cotton. The air is heated by means of gas-burners, and to prevent drying of the wound steam is permitted to enter with the air.

Dr. James McCann, of Pittsburg, read a paper on

SPLENOTOMY.

The paper was the description of a case in which removal of the spleen had been practised, with recovery of the patient.

A paper entitled, "The Study of the Methods of Operation practised and of the Results obtained in the Treatment of Cleft of the Hard and Soft Palates, illustrated by the Record of Fifty Cases," by Dr. J. Ewing Mears, of Philadelphia, was read by title.

A vote of thanks was then extended to the Surgeon-General for the use of the room, to the Cosmos Club for courtesies extended, and to the officers of the Association for the efficient manner in which the proceedings had been conducted.

The Association then adjourned, to meet at the call of the President.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Ninth Annual Congress, held in New York, May 26, 27, and 28, 1887.

Thursday, May 26th—First Day—Morning Session.

The Association met in the Hall of the Academy of Medicine, and was called to order at ten o'clock by the President, Dr. E. Fletcher Ingals, of Chicago.

The roll was called by the Secretary, Dr. D. Bryson Delavan, of New York.

Dr. Ethelbert Carroll Morgan, of Washington, first Vice-President, and Dr. John Nolan Mackenzie, of Baltimore, second Vice-President, were present and occupied seats upon the platform.

MEMBERS IN ATTENDANCE THE FIRST DAY:

Drs. M. J. Asch, of New York; S. H. Chapman, of New Haven; J. Solis Cohen, of Philadelphia; T. A. De Blois, of Boston; D. B. Delavan, of New York; F. Donaldson, Jr., of Baltimore; W. C. Glasgow, of St. Louis; J. H. Hartman, of Baltimore; F. H. Hooper, of Boston; E. F. Ingals, of Chicago; F. L. Ives, of Chicago; W. C. Jarvis, of New York; C. H. Knight, of New York; F. I. Knight, of Boston; S. W. Langmaid, of Boston; G. M. Lefferts, of New York; R. P. Lincoln, of New York; A. W. MacCoy, of Philadelphia; J. N. Mackenzie, of Baltimore; E. C. Morgan, of Washington; C. C. Rice, of New York; B. Robinson, of New York; J. O. Roe, of Rochester, N. Y.; C. E. Sajous, of Philadelphia; C. Seiler, of Philadelphia; B. F. Westbrook, of Brooklyn; E. Holden, of Newark, N. J.; U. G. Hitchcock, of New York; T. R. French, of Brooklyn; and W. F. Duncan, of New York.

The President then delivered the

ANNUAL ADDRESS,

in which he invited the profession of this city to attend the meeting of the Association, returned his thanks for the honor conferred upon him in electing him as the presiding officer, and then referred to the sources of congratulation for the Association. There had been no estrangement from the general profession, and the fraternal feeling had grown stronger and stronger. One source of special congratulation was the good judgment, the zeal, and the untiring energy of the Secretary in his general work, and in his special arrangements for the present meeting.

Dr. Ingals was favorably impressed with the completed arrangements for holding triennial meetings in Washington, as a part of the Congress of American Physicians and Surgeons, and believed that the meetings would be most satisfactory and useful. He then discussed the question of increasing the limitation of membership, the time and place of holding the annual meetings, and the manner of publishing their transactions, believing that the present plan was as satisfactory as could be adopted. He then closed his address with the reading of a paper on

INTUBATION OF THE LARYNX,

in which he referred to the history of the operation, the varieties of instruments that had been used, and then gave the histories of a few illustrative cases, in which was made apparent the rules for *after-treatment* if the best results would be obtained:

First, prohibit all fluids, except by enemata; *second*, give some preparation of mercury in comparatively large and frequent doses; and *third*, in case of the development of bronchitis or pneumonia, give respiratory and cardiac stimulants.

Dr. Ingals then gave a summary of 514 cases which he had collected. Of these there were 134 recoveries; and of these patients many were under three years of age, of which many recovered. Of 52 cases treated by Waxham, of Chicago, in which the patients were under three years of age, twenty-five per cent. recovered, which is a remarkably good showing.

A general conclusion from this *résumé* was that most of those who recovered after intubation must have perished but for the new method, and he felt confident that the percentage of recoveries would be much greater when more care was exercised with reference specially to after-treatment.

According to Dr. Ingals' experience, the O'Dwyer gag was too small, and he had employed Goodwillie's gag, with the additional precaution of wearing a broad steel band around the finger. The operator should be prepared to perform tracheotomy if membrane is pushed before the tube, and also if intubation fails to afford relief.

Intubation can be quickly and easily performed, the parents consenting; no tedious after-treatment is required, and the results, so far, are as good as those of tracheotomy in all ages, and better than from tracheotomy in children under three years of age. A special compliment was paid to Dr. O'Dwyer for his untiring perseverance in his work, and to Dr. Waxham, of Chicago.

Dr. Charles E. Sajous, of Philadelphia, then read a paper entitled

A NEW METHOD OF INTUBATION OF THE LARYNX,

in which he described and demonstrated instruments that he had used on the cadaver, designed to overcome the following objections to intubation: (1) Obstruction of the tube by fragments of membrane; (2) crowding down of loose membrane; (3) passage of food through the tube into the trachea; (4) momentary arrest of respiration; (5) liability to cough the tube out; and (6) slipping of the tube into the trachea.

The advantages claimed for his instruments were that they gave almost the same breathing space as does the normal larynx; that by their comparative shortness they reduced greatly the danger of crowding down the membrane; that the light weight and the shape of the head-piece avoids interference with deglutition, and that the valves enable the patient to breathe freely; that it cannot be coughed out; and that it is almost impossible to force it into the trachea.

The papers were discussed by Dr. Hooper, of Boston, who gave the record of ten cases of intubation in the Boston City Hospital, with two recoveries. In all the cases the relief from the dyspnœa was immediate.

The tubes were coughed up and swallowed in three cases. There was no trouble in feeding the patients, and no difficulty in extracting the tube. In all kinds of cases there had been twenty-eight per cent. of recoveries from tracheotomy in the same hospital.

Dr. Delavan, of New York, spoke of the advantage of feeding by means of a small stomach-tube, and thought that by it the difficulty of feeding after intubation might be largely overcome.

Dr. Asch, of New York, thought that the liability of the false membrane to be crowded down was difficult to be relieved, even by tracheotomy, and that the difficulty of removing the tubes by the general practitioner was worthy of special consideration.

The discussion was continued by Dr. Woodbridge, of Brooklyn; and by Dr. J. Solis-Cohen, of Philadelphia, who regarded it as important to have the patient watched after intubation, and that the difficulty of giving the patients fluids should never be lost sight of. As to the new instruments exhibited by Dr. Sajous, while he did not wish to discourage any effort in the way of improvement, he had seen so many appliances which could be easily used upon the dead body, but which were perfectly impracticable upon the living subject, that he had rather withhold any opinion concerning them until he had found that the device had been used successfully in actual practice.

The discussion was continued by Dr. Chapman, of New Haven, and was closed by the authors of the papers.

Dr. J. Solis-Cohen, of Philadelphia, then described

A MODIFIED LARYNGECTOMY,

by which the entire respiratory portion of the larynx could be removed, and the greater portion of the thyroid cartilages left undisturbed to perform their function as shields. It was applicable to unilateral as well as to the bilateral procedure, and in devising the operation he had been greatly assisted by Dr. Martin, of Philadelphia. The advantages claimed for it were: (1) Rapidity with which it could be performed with comparative safety to the patient; (2) small size of the wound; (3) preservation of the attachment of the thyroid and hyoid ligaments and the several muscles; (4) retention of the functional structures for deglutition; and (5) leaving a firm, natural support for the adjustment of artificial substitutes for the larynx.

NEW INSTRUMENTS.

Dr. DeBlois, of Boston, exhibited a bag with a compartment containing a tank and compression-gauge.

Dr. Morgan, of Washington, D. C., exhibited a universal powder-blower, and also a modification of his uvula hæmostatic clamp.

Dr. Allen, of New York, by invitation, exhibited a laryngeal snare that worked on the lever principle.

The President then appointed the following

COMMITTEES:

Committee on Nomination.—Drs. B. Robinson, of New York; W. C. Glasgow, of St. Louis; and S. H. Chapman, of New Haven.

Auditing Committee.—Drs. Morris J. Asch, of New York; B. F. Westbrook, of Brooklyn; and J. O. Roe, of Rochester.

The Association then adjourned to meet at 3 P.M.

Dr. R. P. Lincoln, of New York, gave the Association an elegant luncheon.

AFTERNOON SESSION.

The Association was called to order by the President, and

Dr. John N. Mackenzie, of Baltimore, read a paper entitled

THE PATHOLOGICAL NASAL REFLEX,

in which he gave a concise and interesting review of the history of the subject as far back as to Galen. Centuries ago cases were reported in which the symptoms, alleged causes, and treatment were very similar to many that have been reported in modern times.

Dr. John O. Roe, of Rochester, then read a paper on

HAY FEVER,

in which he gave an analysis of his cases, together with the results of treatment. His conclusions sustained, substantially, the views which he expressed in 1883, after Dr. Daly had made known that the disease was due in many cases to abnormal conditions existing within the nasal cavities. He has treated forty-two cases, and from the results obtained in their treatment he concludes that the nasal passages must be restored to their natural condition by removal of redundant tissue and destruction of sensitive areas. The indiscriminate use of the galvanocautery was condemned, although it was of great value when properly used, and perhaps chromic acid was the best for destroying the sensitive areas. His conclusions were:

First.—That all cases of hay fever have their initial lesion in a diseased condition of the nasal fossa.

Second.—That disease of these tissues is reflected to other tissues.

Third.—That sensitive areas of the nose are not confined to any particular locality.

Fourth.—That the direction in which the irritation is reflected is always in the line of least resistance, in one direction at one time and in another at other times.

Fifth.—That disease of the nose may produce disease in other parts of the respiratory tract, which may become an independent source of irritation.

Sixth.—That hay fever is due to the effect of local irritation brought in contact with the sensitive regions of the air-passages.

Seventh.—That the disease is not, *per se*, a neurotic disease, nor is a neurotic condition necessary to render patients sufficiently sensitive to local irritation of the air-passages, and it is not necessarily associated with the nervous development.

Eighth.—That the neurotic condition is often developed as the result of the local irritation.

Ninth.—That by careful and judicious treatment of the disease of the nasal tissues and that of other portions of the respiratory passages below and secondarily affected, and by combining with such treatment the systemic medication that may be necessary to remove the general derangement, we need not fail to cure hay fever.

Dr. Sajous, of Philadelphia, believed that superficial organic alteration is of only temporary benefit.

Dr. Mackenzie, of Baltimore, regards the disease as a neurosis, and has had better results when treating it on that basis than when treating it by local means. When he resorts to operative interference he adopts the stellate incision of the tissue in preference to its destruction or removal.

The discussion was continued by Drs. Knight, of Boston; Glasgow, of St. Louis; Holden, of Newark; MacCoy, of Philadelphia; Hooper, of Boston; and Solis-Cohen, of Philadelphia, who said that he was glad to see that the pendulum was again veering toward the right, as it would seem from the tenor of the discussion. He believed that the more the affection was regarded as constitutional, and the less it was regarded as local, the nearer we should get to the truth.

Dr. Glasgow had cured cases by making applications to the larynx alone, and he believed that the mucous membrane of the entire respiratory tract should enter into consideration in the study of this subject.

The discussion was closed by Dr. Roe, who said that Dr. Mackenzie was too sweeping in his statement that all reflected nasal disorders are hay fever, and the same was true of asthma as referred to by Dr. Glasgow. He had been unable to find any evidence that the disease is a neurosis, although a neurotic subject may be more sus-

ceptible to the local irritation which may cause hay fever.

Dr. D. Bryson Delavan, of New York, read a paper on

THE TREATMENT OF ATROPHIC RHINITIS BY APPLICATIONS OF THE GALVANIC CURRENT.

The object of the paper was to bespeak for Dr. Shurly's method, presented to the Association at a previous meeting, a more extensive trial than it has heretofore received. The method consists in applying the positive pole of the constant-current battery to the nape of the neck, and the negative pole directly to the nasal mucous membrane. The chief objection is the time required to carry out the treatment. The electrode which Dr. Delavan employs is of the simplest kind, consisting merely of a piece of copper wire bent to suit the passage and properly protected.

Dr. De Blois, of Boston, had adopted the method with good results in some cases.

The discussion was continued, and turned upon the value of Gottstein's plug, and the weight of opinion was about evenly divided, perhaps with the balance against using any plugs whatever in the nostrils.

Dr. S. H. Chapman, of New Haven, read a paper on

MYALGIA OF THE PHARYNX AND LARYNX.

The laryngeal is less frequent than pharyngeal. It is a muscular and not a sensory affection, and the patients do not show any evidence of disturbance of the general condition. Local treatment has been of no service.

Dr. Frederick I. Knight, of Boston, then opened a discussion on the

SENSORY AFFECTIONS OF THE THROAT.

His experience had been chiefly with hyperæsthesia and paræsthesia. It is important to consider the general condition of the patient in treating these conditions.

Dr. Mackenzie, of Baltimore, insisted on constitutional treatment.

Dr. Jarvis, of New York, spoke of psychical and constitutional causes behind the local affections.

Dr. Sajous, of Philadelphia, had relieved one patient only by local treatment.

Dr. Glasgow, of St. Louis, had seen the cases associated with diatheses, and also inflamed follicles.

The Association then adjourned to meet at 11 A.M. on Friday.

(To be continued.)

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 22 to May 28, 1887.

Hubbard, V. B., Major and Surgeon. Granted leave of absence for one month, to take effect on or about June 1, 1887. S. O. 119, A. G. O., May 24, 1887.

Elbrey, F. W., Captain and Assistant Surgeon. Found incapacitated for active service by an Army Retiring Board; sick leave still further extended until further orders, on account of disability. S. O. 116, A. G. O., May 20, 1887.

Burton, H. G., Captain and Assistant Surgeon. Granted two months' leave of absence on surgeon's certificate of disability. S. O. 107, Division of the Atlantic, May 25, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 28, 1887.

Deane, C. W., Passed Assistant Surgeon. Detached from the Dale and ordered to Hospital, Mare Island.

Harvey, H. P., Surgeon. Orders to Iroquois revoked and wait orders.

Dickson, S. H., Passed Assistant Surgeon. Detached from Navy Yard, Washington, D. C., and ordered to the Dale.

Waggener, J. R., Surgeon. Detached from the Iroquois and wait orders.

White, S. Stuart, Assistant Surgeon. Ordered to Receiving Ship St. Louis, Navy Yard, League Island.

Field, Dr. James G., of Gordonsville, Va., commissioned Assistant Surgeon in the Navy, May 23, 1887.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 28, 1887:

	Cases.	Deaths.
Typhus fever	1	0
Typhoid fever	11	3
Scarlet fever	72	13
Cerebro-spinal meningitis	6	6
Measles	58	6
Diphtheria	116	48
Small-pox	16	4
Yellow fever	0	0

Prognosis in Heart Disease.—Nature's remedy for valvular insufficiency is hypertrophy. We all remember the case of the late Dr. Edgar, of St. Louis, where extensive valvular lesion had been compensated by enormous hypertrophy, and an active life sustained from childhood, when the conditions were first known, to old age. I have the record of a little boy who, suffering from an open foramen ovale, is stronger now in his tenth year than he has been in any previous year.—*Weekly Medical Review.*

Whooping-cough in a Cat.—Mr. O. Bowen, of Liverpool, writes to the *British Medical Journal*: "For the past few weeks I have had under my care a little boy suffering from a more than usually severe attack of whooping-cough, and his mother informs me that for quite a fortnight their cat has had five or six distinct fits of coughing daily, similar in every respect to the boy's, which end after the expectoration of frothy mucus. The cat between the attacks is tolerably bright and active, though not so lively as she formerly was, and has considerably fallen away in condition."

The Causes of Salpingitis.—Dr. Saenger classifies the various forms of inflammation of the Fallopian tubes as follows: I. Forms of salpingitis produced by known specific microbes: (1) Salpingitis gonorrhœica; (2) salpingitis tuberculosa; (3) salpingitis actinomycotica. II. Forms of salpingitis due to specific microbes, identical with those producing traumatic infection: (4) Salpingitis septica. III. Forms of salpingitis produced by specific, but as yet unknown, microbes: (5) Salpingitis syphilitica. Mr. Tait described five causes for salpingitis: (1) Simple catarrh; (2) exanthemata during puberty; (3) gonorrhœal infection; (4) post-puerperal pelvic inflammation; (5) arrested development of the uterus.

Abdominal Wounds.—M. Pozzi communicated to the Chirurgical Society of Paris, at their meeting on December 15th, a case of wounds to the abdominal wall produced by revolver bullets. The patient when seen was vomiting, and passing blood in the urine. Laparotomy was performed; the jejunum and bladder were found to be wounded. The wounded parts were stitched, twenty-nine sutures in all being inserted. The operation lasted two hours and a quarter. The patient died sixty hours after the accident, and fifty-two hours after the operation. —*Medical Press.*

Original Articles.

BOXING THE EARS.

BY SAMUEL SEXTON, M.D.,

NEW YORK.

NEARLY all blows upon the side of the head may injure the ear, and thus range themselves under this category. The custom of ear-boxing is of long standing; thus, according to ancient writers, the classical boxer regarded the ear as the most vulnerable part for the infliction of a blow with the deadly cestus. But, later on, early Christianity aimed a blow against this pagan custom, and with unflinching fortitude the non-combatant, when smitten upon one cheek, meekly presented the other to the still persistent advocate of corporal punishment. And it is due to this kindly example that custom no longer sanctions the practice, though the principle upon which it was founded may have been almost forgotten.

But a great amount of heedless and brutal punishment is still inflicted in this way, not only by pugilists and contestants generally, but also by teachers, parents, and others who find that a punch about the ears is generally a painful and most effectual means of chastisement.

Though corporal punishment, in general, is less in vogue than formerly, the writer has found 51 cases among his records, embracing almost every variety both as regards causation and results, where the ear has been injured by blows of the open hand or fist. Viewed from a clinical standpoint, it was found that 31 of these were males, and 20 were females; of the males, 13 were boxed upon the right ear, 13 upon the left, and 3 of them upon both ears. One was kicked by a companion upon the left ear while bathing, and the right ear of 1 was injured by having the head violently squeezed between the hands of another person. Of the females, 14 were struck upon the left ear, and 6 upon the right. Five of the women were assaulted by pugilistic spouses, which may account for the disproportionate injury to the left ear, since this side is most obnoxious to a right-handed blow.

Though evasive and incorrect answers were often given, inquiries elicited the fact, that of the entire number 8 were boxed in play, 4 by rigorous pedagogues, 2 by parental disciplinarians (the number of these, of course, was actually much greater), and 1, a fervent lover, received a chilling, backhanded slap upon the ear from his indignant sweetheart, effectually cooling his ardor as well as upsetting his equilibrium. The facts in this last case, like many others, only came out long after a misleading statement had been first made.

Several cases occurred among pugilists, the left ear being usually struck in cross-counter. Others were due to assaults, brawls, and contests generally.

The writer, in reflecting on this subject, has been puzzled not a little at the comparatively small number of persons coming to our public clinics with aural trouble produced in the manner under consideration. But when it is considered that but few have any idea of the meaning of the disagreeable symptoms caused by concussion of the ear and its consequences, one need no longer wonder that the injured organ receives no attention. Indeed, it can be readily understood that persons rude and thoughtless enough to box the ears of children will neglect them afterward. Thus but six children came expressly for treatment for recent ear-boxing, though a large number coming for other affections of the ear could recall having had it slapped or pulled previously, and having had subsequently severe pain, distressing noises, and vertigo—symptoms enough, truly, to subdue unruly children, or even a prize-fighter, for that matter.

One cannot lay too much stress on the social aspect of this subject, since the medical adviser may be entirely misled in respect to the causation. Deafness itself is not usually a noticeable feature in children, especially so long as one ear is fairly useful; nor is the yet more distressing symptom of autophonia in its various forms. It is only when pain is unendurable, a discharge offensive to others, or instruction difficult, that the conscience-stricken or reticent parent acknowledges the facts on which a correct diagnosis may be made. A striking case in point occurs to the writer. It was that of a youth, eighteen years of age, who was brought to the New York Eye and Ear Infirmary by his mother, on account of an acute purulent inflammation of the middle-ear with suspicious symptoms of intercranial trouble. He gave the history of a running from the affected (right) ear ever since it had been boxed when he was six years of age. The present exacerbation was due to the rapid growth and consequent pressure of a large polypus. He was advised to have the tumor removed and place himself under treatment, but being very nervous and timid, he lacked courage to consent to the operation. Getting temporarily better, he failed to return.

About a year after this, much more serious vertigo, with other brain symptoms, occurred suddenly, and after a brief illness he died in great agony. The autopsy revealed caries of the petrous bone and pachymeningitis. The father of the boy communicated the final result to me, and with much feeling stated that it was he himself who had struck the blow upon the ear which had thus finally resulted in the son's death. Another case was that of a young man, aged twenty-two, whose father had given him a blow upon the left ear six years previously. Severe inflammation of the middle-ear followed, lasting for two years, during which time the air whistled through a perforation in the drumhead whenever he blew his nose. When seen, the drumhead was found thickened, irregular, and otherwise changed almost beyond recognition. Hearing was very much impaired, and for this relief was sought. In yet another instance of this kind the patient, a young man aged twenty, was slapped upon the left ear by his father. There was immediate pain and deafness, followed in a few hours by a watery discharge, which afterward was tinged with blood. When seen at the Infirmary, two days after the boxing, a perforation in the lower segment of the drumhead was giving vent to a free discharge, and the middle-ear inflammation was complicated with a periostitis externa, the mastoid cortex being swollen, red, and tender to the touch. Autophonia, noises in the head, and pain occurred at the beginning, and were very distressing for a long time, recovery not taking place for three months.

The grave consequences of pounding the ear were well shown in a case of a woman, addicted to drink, aged thirty-eight, who was struck violently by a man upon the right ear in an altercation. The immediate result was severe dizziness, and she had to hold on to a stair-railing to keep from falling. Vertiginous symptoms became more severe, and the pain and autophonia with this alarmed her very much. She was taken to a dispensary, where an energetic attendant, feeling that something must

be done, vigorously inflated the ear by Politzer's method, causing extreme pain in the ear, and afterward introduced some irritant medicament on cotton wool with instructions to keep it in the ear. After this the pain became more severe and she came to the Eye and Ear Infirmary, where the drumhead was examined. This was found to be ruptured. An enormous quantity of serous fluid was escaping from the ear, which was believed to consist largely of the water of the labyrinth, thus indicating that the round window had also been ruptured by the blow. She had now become extremely nervous and experienced insane hallucinations, as was confirmed by Dr. Meredith Clymer, who saw the case. She was admitted to the wards of the Infirmary, and purulent inflammation of the middle-ear soon set in. The cerebral symptoms—pain, vertigo, hallucinations, etc.—became more grave. They seemed due in part to the concussion of the blow; Dr. Clymer thought almost exclusively; but on reviewing the case I am convinced that there was also transmission of a septic irritant through the cerebro-spinal fluid into the cranial cavity, inducing leptomeningitis. The patient left the Infirmary, where her presence proved a great inconvenience to others, before she was well, and when last heard from, a month after the injury, had not recovered.

One not uncommon result of a blow or fall on the ear, might as well be mentioned here. A ceruminal plug is sometimes impacted with considerable force against the drumhead in this manner. The contusion causes pain; if the plug lies long in contact with the drumhead inflammation may ensue.

Rupture of the drumhead occurs not so much in consequence of the *force* with which blows are delivered upon the side of the head as from the violence of aërial compression in the external auditory canal. Blows thus causing sudden concussion may come from above or below the ear, or from the front or rear. Occasionally they fall perpendicularly to the external auditory meatus. In the majority of instances, however, compression takes place through the rapid collapse of the outstanding cartilaginous framework down upon the orifice of the canal. Where the canal is large, condensation is much more effective than where it is very narrow. Pugilists and contestants experience repeated ruptures of the drumhead, and examination of the parts will often show very marked deformities. In two cases observed, the patients exhibited rupture of the drumhead in either ear from blows simultaneously inflicted.

Traumatic injury of the mastoid is said to sometimes rupture the drumhead, but in cases of this kind seen by the writer, while having mastoid contusions, they were, on careful inspection, found to also exhibit evidence of blows upon the auricle at the same time. A very gentle slap, it must be remembered, may, under favorable circumstances, rupture the drumhead, especially in elderly people, in whom it is more friable. Obscure head symptoms, which are often experienced after falls or blows upon the side of the head, so slight that injury of the hearing organ has not been suspected, should therefore suggest an examination of this organ. Boxing the ear, moreover, is known to strain or contuse the drumhead without actual rupture.

Symptoms.—Violent concussion of the drum of the ear gives rise to more or less disturbance of its tension. Numbness about the ear and certain acoustic phenomena, as autophonia and tinnitus, are experienced. The patient at first is usually also confused or stunned. The degree of consequent vertiginous phenomena corresponds to the concussive force and the damage done, but of the fifty-one cases herein cited, only one was actually felled by the blow, and none were made unconscious.

Nervous shock or cerebral concussion is not so great as would be expected when it is considered with what force the indriven drumhead acts upon the ossicles. The stapes, however, owing to the peculiar construction of the transmitting mechanism, cannot be driven with undue force into the oval window in which its base is fixed, though the concussive force from without entirely destroys the drumhead. In extremely violent concussions, however, the drumhead does not always offer sufficient resistance to the force of impact to protect the round window from rupture; its excursions under such conditions may at least give rise to labyrinthine concussion. Such cases are, however, extremely rare as a result of a blow of the hand or fist. Ordinarily the disturbance of equilibrium is slight and of brief duration. Occasionally it lasts for days or weeks, and more or less dizziness may be experienced for an indefinite period.

Pain is usually an immediate symptom, though not invariably so; it may commence only as reactive inflammation comes on, that is so say, in a few hours, or as a result of meddlesome treatment. In intensity it varies from slight discomfort to great suffering. Its duration depends on the extent of contusion, subsequent inflammation, and the nervous temperament of the patient.

Deafness in cases of slight injury may be scarcely perceptible. It is rarely very great at the beginning, and, other symptoms causing more distress, it is liable to be overlooked. It is, for the most part, due to consecutive inflammation of the drum, and therefore need not be considered here. A mere slit in the membrana vibrans scarcely impedes its oscillations in a perceptible degree; nor does contusion of the membrana flaccida. Slight inflammation of the mucous lining of the drum, however, causes greater or less deafness.

Various phenomena, both objective and subjective, attend trauma of the drum of the ear. The sudden and violent tension of the transmitting mechanism gives rise to a sound like the twang of a musical chord, or the sound of a vibrating bell or tuning-fork. Rupture of the drumhead announces itself to the patient with an explosive sound like the rupture of a small bladder or the discharge of a gun. Sometimes the ringing and explosive sounds are both of them heard. Subjective noises supervene, common to middle-ear affections.

Autophonia is a very constant symptom. The resonance of the drum, upon which it partly depends, varies with the degree of swelling and the amount of fluid present. When the ear-drum or other localities in the head reached by the air-passages thus becomes resonant to the voice or other sounds the confusion, and even alarm, of some patients is very great. Patients have come to the writer with the statement that their heads were hollow, and felt empty when tapped with the finger.

Numbness.—The sensitive nerves of the temporal region are often found in a hyperæsthetic state, the parts giving rise to "tingling" sensations when touched.

The progress of these cases, of course, varies. In the 51 cases under discussion it was as follows: 7 were unattended with any discharge throughout; 6 had a serous discharge only, and in none of the above were any inflammatory symptoms observed. In 6 cases there was decided inflammation of the drum and swelling of the drumhead, but no discharge. In 25 cases suppurative inflammation of the drum occurred with greater or less severity. In 6 cases the particulars in this regard were not noted.

Perforation whistle may afford the only intimation of rupture of the drumhead, where a slight blow upon the ear has been given. The escape of air on inflation of the drum, however, is not always of a whistling character, since the quality of the sound depends on the size and shape of the vent in the drumhead and the patulency of the Eustachian tube. Any considerable inflammation of the drum, whereby its lining membrane becomes thickened, thus diminishing its cavity and obstructing the air from the Eustachian tube, or an accumulation of secretions, would affect the character of this sound. The difficult escape of air, or its passage along with fluids, gives rise to peculiar noises, very different from the whistling to be heard several yards away when the drum cavity is dry and the opening happens to be of the proper size.

Appearances.—The drumhead is at first congested, the injection being deepest in the membrana flaccida, and usually extending down along the malleus handle where the network composing the malleus plexus of vessels becomes prominent. But this clears up again in a few hours, unless inflammation ensues, and slight vascularity only remains in the edges of any wounds produced by the injury.

Multiple ruptures occur, but generally they are single and situated in the lower segment—most frequently in the posterior portion of this. They vary in size and shape; often they are triangular, a flap being left attached at one of the sides of the defect. Some are straight, some semilunar or variously curved.

The *course* varies. Large and irregular rents are not always attended by displacement, but when the edges do not approximate any loose flap generally sloughs away and leaves an irregular perforation. The edges of perforations, though irregular at first, afterward become more and more smooth as suppuration continues, and the opening may remain permanently. Where there is displacement only, or where the parts are not kept at rest, healing is delayed; but in the more favorable cases it takes place rapidly by primary union. Meddlesome treatment, of course, protracts the case, and if middle-ear inflammation occurs from this or other cause, affairs become complicated. In the greater number of instances spontaneous and complete union may be expected. Suppuration protracts these cases very much, the reproductive process being slow, and opacities, comprising areas of cicatricial tissue of various sizes, remain. If a large area of the drumhead has been lost a manometric cicatrix often develops itself.

The *prognosis* is favorable in most instances; even where there has been suppuration, the drumhead finally heals. The hearing-power is nearly always restored where a mere rupture occurs. Where there has been suppuration of the drum or other complications, hearing will be more or less impaired. Some of the writer's cases were cured in a few days without remaining injury, while others did not recover for as many months. Several protracted cases were seen where, from neglect or maltreatment, the ear had been discharging for a period of ten years or more. In one case this condition had existed for thirty-seven years. In these protracted cases a great loss of hearing-power existed.

The *diagnosis* is not difficult if the ear is examined early enough, or before inflammation has set in. It is well to bear in mind that the slight traction made upon the cartilage of the external ear, necessary on introducing the speculum, may produce congestion of the drumhead, which is thus made more tense. This congestion is indistinguishable from that caused by boxing or pulling the organ. A perfectly normal drumhead may thus be made to appear to have been injured.

Blood or serum, sometimes both, not infrequently trickle from the ear immediately after the drumhead is ruptured, and when the parts are examined soon afterward, traces of this may be seen. Later on inspissated clots only are usually visible. Sometimes they are limited to the line of fissure and aid in retaining its edges in contact. Where the contusion has been great an area of membrane assumes the appearance of a blood-clot, and may slough or remain while reproduction goes on underneath. In some cases the drumhead swells rapidly, all traces of blood-stained fissures and other landmarks being obliterated. In other cases healing is so rapid that nearly all traces disappear in a few days, so that even an expert can discover them with difficulty. When injuries are not seen until swelling has masked the outlines, they will often be found quite distinguishable again after its subsidence.

Ruptures from boxing occur for the most part in the membrana vibrans, while contusions and lacerations from pulling the auricle occur in the membrana flaccida. If not observed for ten days or a fortnight after the injury the slit-like or ragged-edged wound usually assumes a regular ovoidal shape in cases where suppuration takes place.

A differential diagnosis becomes more difficult when inflammation of the drum, from causes other than traumatic, exists before the injury, or arises subsequently.

The escape of air on inflation of the drum is an infallible sign of perforation of the drumhead; it may be detected with the diagnostic tube when the perforation whistle is not well marked.

I have never seen adhesion of the drumhead to the inner wall of the tympanum take place as the result of injury from boxing the ear, though this may occur as a consequence of severe inflammatory action.

Fracture of the malleus handle.—The appearance of the drumhead a few days after traumatic rupture is sometimes suggestive of such an injury, and the first examination is thus often deceptive. In a case of rupture bisecting the drumhead transversely, examined for the first time nine days after the injury, the malleus handle seemed to be fractured at about its middle; but as the swelling subsided it began to appear that no such injury existed.

In comparatively slight swelling the landmarks become indistinct, or even obliterated altogether; but as healing takes place these are again restored. My suspicions in respect to this injury were not in any instance verified.

Treatment.—It is a safe rule to abstain from doing anything. In most of the protracted cases I have seen, there was given a history of meddlesome treatment from the beginning. When intra-tympanal air renewal is active, as shown by oscillatory movements of the drumhead, the patient should be cautioned against inflating the drum voluntarily, but instructed to maintain rest. When its presence is borne, a quantity of boracic acid with calendula may be introduced by means of insufflation. This, when no discharge, or scarcely any, exists, quickly forms itself upon the membrane, preventing undue motion. The presence of inspissated sero-sanguinolent effusion upon the outer surface of the drumhead affords protection and should not be removed by syringing. In the more protracted cases where the powder is not borne, the instillation of succus calendulæ proves gently stimulating to the granulating edges of the wound, and, on drying, forms a thin, protecting film of calendulin over the wound. The most simple case may be aggravated by active management, such as inflation, syringing, the instillation of irritants, and the like. Inflammation of the middle-ear thus set up cannot, however, be considered in this connection.

The medico-legal aspect of boxing the ear.—Claudius, in pouring a "leperous distilment" (juice of hebenon) from a vial "into the porches of his brother's ear," with murderous intent, could not have done the harm that often follows a thoughtless box upon the ear. Thus it has been shown that the functions of this delicate organ may be greatly impaired by a comparatively slight assault.

Redress for assaults of this kind is sometimes sought in the courts of law. In two cases of recent date coming to the writer's knowledge, the plaintiff was successful in both instances. In one of them, Professor Hjalman Hjorth Boyesen, of Columbia College, was sued in the City Court for $5,000 damages.

The suit was brought by a boy through his father, Alfred E. J. Tovey, editor of the *Brewer's Journal*, his guardian *ad litem*, before Judge Hawes and a jury. It was stated that defendant struck the boy, who was then seven years of age, on the head. From the testimony, as reported in the *Times* newspaper of May 6, 1885, it would seem that the boy received a slap with the hand which did not knock him down. The father testified that his son was not deaf prior to the assault, and that he had since been under medical care. It was suggested by the defence, which contended that only a gentle slap had been given, that the trouble might have arisen from

colds, or from having bathed in the sea. A witness testified that the boy went into the water too often, and that he was slightly deaf before the assault.

The jury decided that the defendant must pay $400 damages.

In another case, Marwig *vs.* Davies, large damages were claimed; the case was settled by the defendant consenting to the entry of a judgment. Mr. Newcombe, the plaintiff's counsel in this case, states that the "defendant struck the child—he fell on a rock—producing temporary deafness. Our action was for the assault."

As medical jurists, we must bear in mind that the extent of aural injury, where the patient has been assaulted by a blow upon the side of the head, is not to be measured by the *force* of impact, but rather by the *nature* of the blow. Thus, in one instance the force of a violent assault may expend itself without injury of the hearing-organ, while in another a very slight tap upon the temporal region, by suddenly compressing the air in the external auditory canal, may contuse and rupture the drumhead. It has been said already that a simple rupture should be let alone, since in healthy persons it soon heals. It is the purulent inflammation that ensues in catarrhal subjects, or from mal-treatment, that causes most of the trouble in these cases. In persons with general catarrh of the upper air-tract, traumatic injuries of the ear seem disposed to suppurate. Head catarrh, coming on subsequently to trauma, like injudicious treatment, will generally protract these cases very much.

Where a traumatic wound of the drumhead has in this manner become chronic, so to speak, a diagnosis is difficult. Hence, in order to determine the exact degree of injury from traumatism, an expert examination must be made early. Thus, where an examination has been postponed, the rupture no longer presents a slit-like appearance, but has assumed a more or less ovoidal shape, and cannot now be distinguished from perforations due to chronic purulent inflammation from causes other than traumatic.

It appears to the writer that the assailant is not the only person to be held accountable for the results of injudicious treatment or neglect; for, although the legal rule, in New York at least, as to liability in actions for damages for injuries to the person arising from tortious acts seems to be, that although the original tort-feasor is ordinarily liable only for such consequences as naturally flow from his wrongful act or negligence, and not for those injuries due to an intervening and intelligent cause, still, if a plaintiff, suffering physical harm from the wrongful act or omission of the defendant, calls in good faith such medical attendance as it is reasonable to presume would be competent to effect his cure or restoration to health, and the physician or surgeon, so called, by erroneous treatment causes positive harm, the plaintiff shall nevertheless recover in the action. At the same time, a jury being the arbiter of the measure of damages, it may be less likely that a large verdict would be recovered against the original tort-feasor in many cases than against the physician, if the latter's malpractice could be established; and the plaintiff, having an action against the medical attendant, who is bound to exercise at least the skill and knowledge possessed by the average practitioner of his neighborhood, may often find him a more desirable defendant, especially if pecuniarily responsible, than the original wrong-doer, although the latter may be also responsible at law.

It is important to ascertain if there has been deafness or a discharge from the ear before or at the time of the alleged injury, and if so, whether any increase of the trouble was caused thereby. This is a point concerning which reliable evidence must, in many cases, be entirely wanting or difficult to obtain, since both may exist without the patient's knowledge. Nor is the testimony of others in this regard always competent, for both teachers and parents, where children are concerned, may have no suspicion of deafness where it actually exists, so long as one ear remains sound, or even fairly so. Where the ears have been pulled and boxed repeatedly, some impairment of the organ of hearing is nearly always found, and often very pronounced in degree. But where the injury has been but slight and confined to the drumhead, with rapid recovery, hearing is usually completely restored. In ascertaining the loss of hearing-power the voice is the best test, for the inability to converse is a greater detriment than not to be able to take cognizance of other sounds. Malingering may be resorted to by the complainant, but unless cleverly done is not liable to deceive the expert examiner. This, however, is a device seldom practised unless absolute deafness is claimed, a result seldom following boxing of the ears. Where great deafness is claimed to result from trauma, the drumhead should be carefully examined for evidence of resulting deformity, using if necessary a magnifying lens.

The question of permanent injury from shock is likely to come up in some cases. Everyone knows that falls and blows upon the head often give rise to vertiginous phenomena, but serious labyrinthine concussion as a complication of ear-boxing is comparatively rare, since the concussive force from blows with the hand or fist is broken by the drumhead, thus protecting the round window. Acute inflammation of the middle-ear consequent upon trauma, as from other causes, is very often attended with vertigo. In cases where purulent inflammation of the middle-ear has followed trauma, vertigo, autophonia, and various forms of tinnitus, as well as deafness, may remain permanently. It is well to remember that deafness from chronic catarrh of the middle-ear is much more likely to be found on the left side.

12 West Thirty-fifth Street.

A PLEA FOR EARLIER OPERATIONS IN PERITYPHLITIC ABSCESSES, WITH A CASE OF LAPAROTOMY FOR PERFORATION OF THE APPENDIX VERMIFORMIS.[1]

By ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL; CLINICAL PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

A PHYSICIAN in full general practice soon becomes possessed with the clinical knowledge that the inflammations beginning in the right iliac fossa, which he has been taught to consider as perityphlitic, do not always run the same course. At times beginning with pain of great severity, symptoms of general peritonitis rapidly ensue, which, masking the iliac pain, quickly pass on to a fatal termination in from one to five or six days; or, in lieu of this latter, with almost equally marked constitutional disturbance, the general peritoneal tenderness, while considerable, remains overtopped by the original pain in the right side, and on its subsidence, as time passes, a tumefaction in the iliac fossa is revealed, which, with some recurrence of chills, progresses with fair rapidity toward the surface, and soon shows itself unmistakably as an abscess. However, instead of this form, he may be called to treat a case of fairly sharp pain, infrequent vomiting, and some intestinal distention, but no general abdominal pain nor parietal rigidity, and with easily and early recognized right-sided swelling, which, with the usual symptoms, after a number of days shows itself to be an abscess. Or, finally, he may encounter a patient suffering with pain of a variable character, not always to be distinguished from that of the immediately preceding type, and with this a sensitive swelling is quickly felt, with moderate temperature-elevation, which latter promptly subsides under the use of anodynes, and throughout the course of the trouble but little inflammatory peritoneal symptoms are to be appreciated, though obstructive signs may be present. In this latter case resolution is common.

[1] Read at a meeting of the Practitioners' Society, May 6, 1887.

The explanation of this variation of symptoms is not difficult; the researches of Treves[1] had shown us that the cæcum and its appendix are covered entirely by peritoneum, and that they both are also entirely intra-peritoneal viscera. This is contrary to the usual teaching—which is, that the posterior part of the caput coli is destitute of peritoneal covering, and is attached to the fascia covering the right iliacus muscle by areolar tissue.

Treves, from an examination of one hundred bodies, has found that in every instance the cæcum and appendix has been completely enveloped on all sides by peritoneum, and has been free in the abdominal cavity. Furthermore, there is no such thing as a meso-cæcum. The mesenteric attachment, which is not always met with in the appendix, is derived, evidently or primarily, from the terminal portion of the ileum. The point of the appendix, it is known to all, does not in every case hang down in the pelvis, and as it varies in length, it also varies in position, and can attach itself by slight inflammatory attacks to contiguous organs; but in eighteen per cent., as a normal procedure, it is glued posteriorly, more or less tightly, to the cæcum. These anatomical facts, with the pathological one stated by Fitz,[2] that only three cases of acute primary perforation of the cæcum have been found on record, which statement is confirmed in Matherstock's exhaustive article on perityphlitis, lead directly to the conclusion that the so-called perityphlitic abscesses are due, in the vast majority of instances, to inflammation[3] or perforation of the intra-peritoneal appendix vermiformis.[4] Now this latter, which is the more common lesion, can act in three ways: The opening may allow extravasation of fæces or gas, or of the more infectious products due to necrotic processes (Grawitz), into the peritoneal cavity, with the result of a fulminating peritonitis; or, what is the most common of all the conditions from the lesion in question, the adjacent intestines may become speedily adherent to each other and shut off the inflammatory focus from the rest of the peritoneal cavity, and in this way an intra-peritoneal abscess is formed; and, lastly, by virtue of old or recently formed adhesions of the appendix and cæcum (and this seems to be more common on the posterior surface of the latter) to the parietal peritoneum, the contents of the perforated appendix may enter the sub-peritoneal cellular tissue and there develop a swelling and abscess. These intra-peritoneal abscesses are spoken of by With,[5] who has written most ably on this subject as local appendicular peritonitis, and who met with 16 of this character in 35 personally observed cases. Sands,[6] however, says that he has operated for perityphlitis a great many times, but had never yet found a circumscribed abscess bounded simply by coils of adherent intestine. My own experience is in the reverse direction, for I have, out of six cases of perityphlitis seen in the past year, been able in four instance to recognize toward the median side of the abscess, after it had been opened, the irregular loops of small intestines, which thus proved the intra-peritoneal nature of the abscess. On this point, also, Fitz speaks in no uncertain manner, viz.: "The adherence of coils of intestine to each other and to the abdominal walls favors the accumulation of the exudation in a limited space, and thus the formation of the tumor."

[3] With, among others, regards the existence of a primary typhlitis as very doubtful—the group of symptoms attributed to this disease belonging to an intra-peritoneal abscess.

[4] Taft states that, in three hundred personal observations, every third person between the ages of twenty and seventy showed traces of inflammatory trouble, past or present, in the appendix, and that actual ulceration existed in five per cent. of all bodies examined by him. In Noyes' collection of 100 cases of perityphlitic abscess treated by operation (Trans. Med. Soc. R. I., December, 1882), I find, by analysis, that there were 40 cases in which concretions or foreign bodies were found, 14 cases where much air was met with, 45 where pus, more or less fetid, was evacuated, and 1 in which it is not noted. This proves very clearly the fact of perforation being very common.

[6] Sands: Medical News, January 15, 1887.

These remarks of his, it must be recollected, are based upon the careful consideration of 257 cases of perforation of the appendix vermiformis. Again, he says that the more protracted the course of the disease the greater is the probability of the destruction of the peritoneum forming the wall of the abscess. With this perforation of the parietal peritoneum, he adds, purulent and fecal infiltration of the abdominal wall may occur. It is rare, he also further remarks, for the primary swelling to be paracæcal, although this variety occurs where the appendix lies behind the cæcum. This point of the location of the abscess will be of comparatively little importance to those who believe in the dogma, "Ubi pus ibi evacua"—"when pus is found, let it out"—but is of great moment when the advice is listened to of delaying an operation for the relief of a perityphlitic abscess until the twelfth to the eighteenth day,[1] as the risk thus incurred is by no means small. For out of 176 cases given by Fitz, thirty-four per cent., or 59, died during the first five days, and out of the 35 cases observed by With, 12 died in periods of from two to six days; and in children this mortality reaches to the high figure of seventy per cent., and forty-four per cent. die within the first three days, according to Matherstock.[2] Hence the need of early interference to avail anything in such cases.

There is another risk which comes from waiting, which I beg to refer to. It is the bursting of the abscess into the peritoneal cavity and the lighting up of a general, and usually fatal, peritonitis. This happened in one of my earliest cases. Ball, in his able thesis, out of 67 collected instances, found that this occurred eight times. A fit of laughter, in one of With's cases, produced a similar disastrous result. It often occurs on the fourth to the fourteenth day, without the tumor being detected, and took place in 6 of With's 12 fatal cases.

The principal objection that has been raised against the early operative interference, which is the natural deduction from the foregoing statements, is that an iliac incision, made to reach a deep abscess, might involve or open the peritoneum, which then might be contaminated by the evacuated pus; in other words, that the operation itself is unsafe, and, secondly, that, owing to the subsidence of a certain number of iliac swellings, resort to the knife might be unnecessary. As to the risks that may be brought about in operations for the relief of either sub- or intra-peritoneal abscesses, such are frequently and happily overcome by the gynecologists in the treatment of peritoneal abscesses of other causes; and in extirpation of the rectum, with the common opening of the peritoneal cavity, the influence of infectious fæces is easily guarded against. Moreover, it should be proved, which is, however, not done, that this supposed danger is greater than the actual ones already enumerated. Furthermore, as to the subsidence of perityphlitic tumors this is granted, and takes place, too, not infrequently where the abscess is undoubtedly present, as is shown in Ball's cases, where it occurred fifteen times by perforating into the cæcum—a result not always to be recognized by subsequent inspection of the fæces. This occurrence does not militate against an early opening of the abscess by the surgeon, but rather works in the opposite direction, as the perforation might occur in other more dangerous regions—*e.g.*, into the bladder, etc. Another explanation for the subsidence of cæcal swelling is afforded by the fact that such (the fourth condition alluded to in my opening remarks) conditions are often due to a cecitis of fecal or possibly infectious cause. They can usually be distinguished by their more gradual development and the prompt subsidence of the acuter symptoms under the use of anodynes. They are not always as readily made out as writers would lead one to suppose. So acute a surgeon as Dr. R. I. Hall,[3] of this city, was misled by a similar case, which was subsequently cleared up by a free

[1] Sands, quoted by Noyes: Trans. R. I. Med. Soc., 1882.

[2] Gerhardt: Handbuch der Kinderkrankheiten, Bd. iv., c. 912.

[3] Medical News, May 22, 1886, p. 582.

but late evacuation of the bowels. It may be here remarked that, in cases of perityphlitic trouble where a doubt exists, it is wiser to refrain from moving the bowels, as this might, in a perforative effusion, precipitate a general peritonitis. Kraussold[1] scouts at the idea of resorption of a perityphlitic abscess, and says that where it takes place, and not by internal rupture, no abscess has existed.

A final quotation on this part of my subject may be made from Pepper,[2] who states that "the unjustifiable delay permitted in many cases of typhlitis, while hoping day after day for the more definite detection of suppuration, is the direct cause of many avoidable deaths."

In consideration, therefore, of the foregoing data, it seems to me justifiable to urge the necessity of opening all inflammatory swellings of the right iliac region as early as possible. The detection of pus may be frequently aided by the use of a good-sized aspirator-needle, carried in several directions and into the lumbar region as well as deep into the iliac fossa. But recollect that even though the aspirator fails to show the presence of pus, it by no means proves that it is not there. If the tenderness is too great for satisfactory palpation, an anæsthetic should be administered and the iliac region carefully but gently examined; to this should be conjoined a rectal exploration. If a tumor be made out, in such circumstances, the use of an exploratory incision, running as if for ligature of the external iliac artery, or, as Burchard[3] suggests, one starting two inches in front of the longissimus dorsi muscle and running forward just above the iliac crest, can be resorted to until the swelling is reached, when either aspiration can again be used or the tumor can be directly incised. If any exploration of the cavity is employed, it should be very carefully conducted, to avoid breaking down protective adhesions. This exploratory incision in doubtful cases should be carried well back, so as to allow the post-cæcal region to be fully examined.

Fitz directs that such operative measures should be conducted as soon as the abscess becomes evident, and that this is usually on the third day after the appearance of the first characteristic symptom of the disease. Kraussold also advises the earliest possible incision, to prevent dangerous complications. By resorting to aspiration, Bull was able to detect and open a perityphlitic abscess on the second day after the first symptoms had developed. In concluding these reflections on the treatment of perforations of the appendix, with abscess-formation, one must not be misled by the statistics of operations successfully done at comparatively late periods of the disease, as, for instance, is given in the 100 cases of operations collected by Noyes, in which there were but fifteen deaths; but even here, in the 12 cases that were incised on the eighth day or earlier, the mortality was but eight and one-half per cent., while in the 88 other cases later operated on the death-rate rose to seventeen per cent. The figures already given have shown how great is the mortality without operation prior to the fifth day even, and it is in the hope that many lives now lost may be saved that the persistent presentation of the question of early surgical interference to the profession is made.

But much heavier responsibility comes upon the surgeon when his judgment is called upon in the cases where an acute general peritonitis is supposed to be progressing from a perforated appendix. In some instances, styled by Mikulicz the per-acute, the peritonitis may destroy life within forty-eight hours—generally it lasts from three to six days, and occasionally longer. It may begin frankly, with sudden and violent abdominal pains, felt early in the right iliac region, but soon masked by the general peritoneal tenderness (in this differing from the intra-peritoneal abscess, which commonly has the most intense pain in the affected iliac region). Nausea soon appears, with vomiting, first of bilious matter, which often becomes fecaloid and occasionlly stercoraceous, thus simulating an obstruction. There is high fever, going to 104° and over; the abdomen at first is hard and rigid, a point that Ebstein[1] lays stress on as indicative in such conditions of a general perforative peritonitis; it subsequently becomes tympanitic. The liver-dulness[2] is but little changed, unless tympanites has set in. There may be painful micturition, or even complete retention. The pulse ranges from 90 to 140 and becomes, though not always early, rapid and small. Constipation is usually present, with the other usual signs of intense peritonitis. Percussion reveals no dulness, and under anæsthesia no tumor can be felt about the cæcum. Late in the progress of the disease flatness or percussion in the flanks will occasionally mark the presence of peritonitic fluid. All these symptoms may likewise develop themselves in the course of a mildly progressing or less severely acute local iliac peritonitis. In the one to be immediately reported, the exacerbation of pain showed itself at the end of the second day. Rarely do such symptoms satisfactorily ameliorate. With had 14 of these cases, of which 2 recovered. Pepper, out of 12 cases, had 6 of this kind, of which all died. Matherstock reports in this connection that in children, in whom this general peritonitis is more common, forty-four per cent. of the cases of perityphlitis die within three days; while Whittaker[3] gives the mortality in adults at the lower figure of thirty per cent.

It is quite natural, therefore, that surgery should be called on for help in such a grave disease as this, in which nearly all authorities speak in the most discouraging terms. It is only lately, however, that an endeavor has been made to reverse the death-record in this lesion. It is true that gynecologists, commencing with Keith[4] in 1865, and embracing the noted names of Wells, Schröder, Tait, and others, have repeatedly performed, with success, laparotomy with fully developed general peritonitis. Tait even has expressed himself axiomatically that the presence of peritonitis, together with some other condition which by itself would involve abdominal section, is the most potent of all reasons for the immediate performance of abdominal section;[5] and in another journal he dogmatically remarks further, in connection with obscure abdominal diseases, and this is quoted with approbation by Albert, of Vienna, that when the doctor is in doubt and the patient in danger, make an exploratory incision and deal with what you find as best you can.[6] Led by the experience that produced such logical conclusions, surgeons have essayed, in the infectious peritonitis produced by perforations of the intestines, to resort to laparotomy, with, so far, much inferior success to that attained by their gynecological brethren. Up to the present time this operation has been performed for perforation of the intestine, not traumatic, fifteen times, in nine of which the perforation took place in the appendix. These latter are epitomized as follows:

Case I.[7]—Mikulicz, 1883; male, aged forty-nine. Laparotomy on fifth day, for general peritonitis, from supposed intestinal obstruction. Perforation not recognized at operation. Death on fifth day. Perforation of appendix found at autopsy.

Case II.[8]—Chaput, 1883; male. Laparotomy, tenth day, for supposed obstruction. General suppurative peritonitis; drainage. Death shortly after termination of operation. Perforation of appendix found at autopsy, which had not been recognized at operation.

[8] Progrès Médicale, 1883, p. 103.

Case III.[1]—Krönlein, 1884; male, aged seventeen. Laparotomy, second day, with all usual signs of peritonitis present. Temperature not high, nor was there much tympanites present. Appendix found perforated, and removed for first time in history of surgery. Patient died on the second day after the operation, after a temporary amelioration of symptoms.

Case IV.[1]—Krönlein, 1885; male, aged seventeen. Laparotomy, eighth day. Early symptoms pointed to right iliac disease. Stercoraceous vomiting and great tympanites came on, and induced operation. The perforation was not found. Belly cleansed and closed without drainage. The patient recovered.

Case V.[2]—Polaillon, 1884; male, aged nineteen. Laparotomy, seventh day, for supposed obstruction of the bowels, with fully developed peritonitis. Perforation not found, as the source of obstruction was not recognized. A loop of intestine was sewed in abdominal wound and an artificial sinus there made. Death occurred ten hours later—only at the autopsy was the perforation of the appendix recognized.

Case VI.[3]—Poncet, 1885; male, adult. Laparotomy, fourth day, without anæsthesia, with general peritonitis and fecal vomiting. Perforation not found. Only an ulceration of the mesentery recognized, probably secondary. Drainage. Died same day. At autopsy appendix found gangrenous, but not perforated, but containing several fecal concretions in it.

Case VII.[4]—Regnier, 1886; male, aged sixteen. Symptoms of intestinal obstruction, with stercoraceous vomiting. Laparotomy, fifth day. Suppurative peritonitis found. Died seven hours after operation. Perforation of cæcum only recognized at the autopsy.

Case VIII.[5]—H——, 1886; male, aged eleven. Fifth day, laparotomy over most tender spot in right iliac fossa. Healthy intestine exposed; by poking with fingers an abscess containing two ounces was opened, and drained. The patient recovered.

Case IX.[6]—R. I. Hall, 1886; male, aged seventeen. Laparotomy, fourth day. Present, acute peritonitis, with a right inguinal hernia. The diagnosis of strangulated hernia was made, the sac was opened, and gave exit to fetid pus. At top of sac cæcum was recognized and a perforated tubercular appendix vermiformis, which was tied off and removed. The wound was enlarged upward three inches and the cavity of the peritoneum opened large enough to admit the hand, by which a number of purulent deposits of pus were broken up and emptied, but no washing out resorted to. Large drainage-tube and vent of iodoform-gauze used. Patient recovered.

Case X.[7]—Bryant; male, aged forty-nine. Laparotomy, end of second day. General peritonitis, with referred epigastric pain. Operation discovered the appendix perforated in three places. Peritoneal toilette and washing with $\frac{1}{10000}$ sol. bichloride. Death twelve hours later.

To these cases, collected in a rather hasty search through medical journals, can be added two cases of my own in which similar operations were done and with, in each instance, a fatal result. One of these cases has already been reported in *The Medical News* for January 15, 1887; in this instance laparotomy was resorted to on the fifth day of the disease, and on the same day that he entered the hospital. An aspirator-needle drew pus from right iliac fossa and an incision was there first made, though no dulness existed, in the hope that a circumscribed collection of matter might be encountered. It proving to be a general suppurative peritonitis, a median laparotomy was done and a perforation of the appendix recognized very easily. This was sewed, after a previous ligature, to its base, and the belly washed out and drained. Death occurred suddenly six hours after the operation, after temporary improvement under stimulants and tincture of strophanthus, and on the autopsy a ruptured aortic valve was found.

My second case was as follows: A hearty young man, nineteen years of age, who had had twice within the past two years colicky pains and some prolonged tenderness in the right iliac fossa, was seized, Monday evening, April 18, 1887, with pain in the same region sufficient to cause him to bend over in walking. This pain during the night increased, and the next day extended more over the whole belly. He had that day an enema administered, without effect. The next day, in the afternoon, a chill came on, with aggravation of symptoms. Pulse ran up to 130 and temperature to 104°, and the tenderness of the abdomen, which had heretofore been greater in the right side, was felt more to the left of the median line. Vomiting occurred only once this day. He was seen by a surgeon in consultation with his regular medical attendant, and a number of leeches were ordered to be applied to the right iliac region, and opium and antipyrine to be administered. I was called to see the patient, April 21st, on the fourth day. His pulse then was 136 and of good, strong character; no vomiting, no anxiety or pinching of the face. He had, however, a tense, hard abdomen, with but little tympanites, no diminution in the liver-dulness, and decidedly marked pain, without any change in percussion-note, to the left side of the median line. No irritability of the bladder. There was only a moderate amount of pain in the right iliac fossa, where, moreover, no flatness in sound could be elicited or tumor detected. Believing that I had to deal with a perforated appendix, with a possibly forming intra-peritoneal abscess, I prepared a laparotomy, after a more satisfactory examination under an anæsthetic, and he was sent, therefore, to the New York Hospital. Two hours later he was there etherized, which allowed, by relaxing the taut abdominal wall, a freer palpation. No tumor could be made out, and a further effort to discover pus was made by thrusting in a fair-sized aspirator-needle in three different directions in the iliac fossa. Nothing resulted from this, and on consultation with my colleagues, Drs. Markoe and Peabody, it was judged that the absence of vomiting and of the characteristic symptoms in the face and pulse warranted a delay of twenty-four hours, in the hope that we had to deal with a localizing inflammation. I felt myself justified in agreeing with them, though the events to be narrated showed the danger of so acting; for during the night bilious eructations and vomiting came on with increasing frequency, and turned rapidly to a fecaloid fluid, though destitute of stercoraceous odor. Tympanites also developed, with augmented rapidity of the pulse and with a peritonitic face, but with a lessened temperature to 102°.

When seen by me at noon the next day, it was evident that laparotomy afforded him the only hope, and that but a slight one, of relief. The patient's relatives were acquainted with its risks and its faint hopes, and they requestedits performance. This preliminary action delayed the operation till 3 P.M., when pulse was 132, temperature 99½°, and symptoms as before narrated.

An incision, at first three inches long, was made into the peritoneal cavity, and subsequently enlarged after an abscess had been detected at the brim of the pelvis, which broke under the finger's touch and allowed the escape of five or six ounces of fetid yellow pus to run over the already inflamed intestine in the pelvic cavity and adjacent parts. After the incision had been enlarged the pelvic cavity was rapidly washed out with quite hot water, and as quickly dried with sponges. The intestines were then pulled aside from the iliac fossa and the appendix exposed. To do this several feet of tympanitic small intestine had to be withdrawn from the peritoneal cavity and were kept under warm, wet towels. The appendix stood up like a child's erect penis, and was seen *in situ* to

be perforated in two places. It was seized with a clamp forceps and a silk ligature carried above the forceps close to the cæcum, and after this the appendix was cut off. In the smaller and higher perforation was a mass the size and shape of a grape-seed, but which, after examination, proved to be, as is usual, a fecal concretion. The other opening was lower down and was the size of a large pea. The abscess ran from the pelvic brim across the top of the bladder, and between it and the rectum, and so near to the iliac vessels that its detection by an aspirator-needle would have endangered them. A glass drainage-tube was carried to the depths of the pelvis and another of rubber was placed in contact with the stump of the appendix, which also had been dusted with iodoform before the abdominal wound was closed. The drainage-tubes emerged from the lower angle of the wound. It had been intended to make an opening in the anterior spine for the rubber tube, but it was found to be unnecessary. The peritonitis was more marked in the inferior segment of the peritoneal cavity. The effect of the hot-water douching was unfavorable rather than otherwise. They were used not only for unantiseptic cleansing purposes (having been cooled by time from a boiling point), but also for their stimulating action, as has been claimed for such by Dr. Wylie and others. They were noticed to be associated each time with a marked deterioration of the pulse. It may have been that the heat was too great, as at first it was sufficient to be decidedly uncomfortable to my hands and those of my assistant colleague, Dr. Bull. The patient was much shocked by the operation and died four hours thereafter, with a temperature running up to 105° before death. The autopsy revealed nothing of additional moment.

In summing up these cases, it will be seen that of the twelve only three recovered, but Homan's case should be excluded from the list, as it properly belongs to the class previously commented upon where a tumor existed. It, however. bears strongly on the point of the comparatively slight risk that exists of infecting the general peritoneum in opening such abscesses by lateral laparotomy. Hall's case also, while brilliant in its results and in its treatment, might be relegated to a different class, as it had, as an incentive to the operation and as a guide, a distended hernial sac. A peculiarity of special interest is seen in the frequency with which stercoraceous vomiting occurs in these severe perityphlitic cases. It was first alluded to by Krönlein, and I have been struck by it in my investigations in other cases which were not operated on. It was met with, also, in the case of our lamented friend, Dr. Griswold, in whom, by autopsy, there was observed a perforated appendix, and in whom the symptoms were generally obscure. It is supposed to be due, in some instances, to the pressure exerted by the abscess on the terminal or fixed portion of the ileum. This feature is also mentioned by Duplay as one of the rare symptoms of a general peritonitis. Whether anything of a pathognomonic value should be attached to it in connection with a right iliac pain cannot yet be said, but in every laparotomy resorted to for obstruction the region of the appendix should be investigated. I had hoped, in reviewing the histories of abdominal section for perforations, encountered elsewhere, of the intestines—seven in number, with three recoveries[1]—that I might be able to show that the improved mortality in such cases was due to the promptness with which the belly was opened after the appearance of the first symptoms. This was only seventy-two hours in Mikulicz's celebrated case, but in Schroeder's equally successful case this point is not mentioned. Israel's case was somewhat like Hall's, but no perforation was recognized, and is considered by Mikulicz as a doubtful case. One cannot but help feeling, however, that this is an important factor in the treatment of similar rapidly progressing cases. The exhaustion of the system from such an acute infectious process as a septic peritonitis must be extremely great, and to add to this the shock of an extensive operation places the chances of recovery at great odds. Whether this can be offset by increased acuteness in diagnosis or improvement in surgical manipulations remains to be seen.

Concerning the recognition of a general perforative peritonitis, it must be admitted that many difficulties yet surround this point, but it must also be kept in mind that a serious inflammation from such causes often proceed, and rapidly, too, without many of the ordinary symptoms of peritonitis. Pain is often wanting; the same may be said of the vomiting, etc. The main purport of these remarks is to direct attention to the need of more boldness on the part of the surgeon.

Personally, with the light of experience, I should hope to make hereafter earlier resort to explorative incisions in conducting the treatment of an obscure peritonitis or of an obstruction, and would lean with more weight than some of our older surgeons and physicians do, upon what appears to them the somewhat extravagant advice of the so-called abdominal surgeons or "belly-rippers." For it appears that those most clamorous for early abdominal section are the ones who have done it most frequently, and those who protest are the ones who resort to it least; and, further, one prominent laparotomist does not, from his gathering experience, contradict the teaching of a rival laparotomist, but continually confirms it. I go over this line of thought to relieve myself from the charge of rash judgment in advocating an operation of risk in cases (1) where it is possible that delay might permit a less serious one to be performed, as in the cases of early tumor, with signs of peritonitis; and (2) where the conditions seem to be hopeless of recovery, as in those of rapidly progressing general peritonitis. Passing this by, let us ask if perhaps a variation in the surgical procedures may not be of service? In order to avoid the deterioration that comes from anæsthesia, not only in the weak state of the patient, but also with a much uplifted diaphragm, I propose hereafter either that the anæsthesia should be done away with or limited as much as possible, or cocaine substituted for it. When a general anæsthetic is given, a previous injection of atropia, one-sixtieth, with morphine can be given with advantage in this and other respects. If after the small lateral or the median laparotomy incision is made a localized peritoneal abscess is reached by the finger, as in my last case, I am inclined in my next trial, as the peritonitis often becomes less intense the farther one goes from perforation, to content myself with placing a drainage-tube in the pus-cavity and trust to the less violent methods rather than to the surgically correct procedures of washing out and sponging the peritoneal cavity, or, as Krönlein did, of wiping carefully off all the patches of lymph from the intestinal loops, etc. That it is not necessary to close up the opening in the appendix, or to remove it, is fully proved by the numerous cases of recovery where perityphlitic abscesses have discharged for some time fecal matter, and also by the preponderance of spontaneous closure observed in the larger openings found in gangrenous hernias.

Should reasons exist for more thorough work than this, and the patient's strength permit, not only might the appendix be properly tied off, but the recently made suggestion of Albert[1] may be employed. It is, as the ordinary drainage-tube can only act generally but a very short time, in consequence of the agglutination of the intestines, that a number of such tubes should be carried by small puncture through the abdominal walls into different places among the intestines. A second opening, when a median cut has been made directly over the cæcal region, certainly affords more direct drainage, as my first case exemplified.

[1] Mikulicz (recovery), Schroeder (recovery), Oberdt, Krönlein, Lucke, Godlee, and Israel (recovery).

[1] Wien. Med. Ztg., No. 10, 1887.

In recapitulation, I venture to propose:

1. That the generality of perityphlitic abscesses are due to inflammation or perforation of the appendix vermiformis.

2. That the mortality in such lesions is greatest prior to the third day.

3. That as soon as it can be recognized, pus should be evacuated extra-peritoneally, if possible, or by a lateral laparotomy, and the cavity drained.

4. That if aspiration fails to detect pus where a tumor exists, it is wiser to make an early extra-peritoneal exploratory incision.

5. That where general peritonitis is progressing, with any history of a right iliac pain, a limited lateral (preferable) or a median laparotomy should be made, to explore the region of the appendix within forty-eight hours from the inception of the disease.

6. That if pus is thus recognized, it should be evacuated and a drainage-tube inserted without toilet of the peritoneum.

Progress of Medical Science.

An Intermittent Form of Meningitis.—Dr. Henoch has described a moderate form of simple, non-tubercular meningitis, characterized by a protracted course and by alternations of exacerbation and improvement. The onset is sudden, the fever being more or less intense, with frontal headache, sometimes vomiting, and always marked rigidity of the muscles at the back of the neck, which may sometimes affect the muscles of one or other side. The fever abates, and improvement occurs after one and a half to two weeks, to be followed by a renewed exacerbation, after an interval varying from twenty-four hours to several days, without any apparent cause. These variations may be repeated frequently in the course of the next few weeks, cure resulting in from seven to ten weeks. Cases in which the remissions are not marked usually end fatally, especially when they occur during the first year of life. Treatment appears to have little or no effect on the disease, and its etiology is frequently obscure, although sometimes it seems to depend on some infectious cause. Flexion of the knee-joint, with the thigh at right angles to the trunk, as described by König, is not always present.—*The British Medical Journal.*

Phagocytes.—The suggestive doctrine that cells and bacteria are opposed to one another in a struggle for existence within the body, based upon the remarkable property possessed by leucocytes of devouring foreign material in contact with them, and employed to explain the phenomena of inflammation, the formation of giant-cells and of specific neoplasms, as well as to account for immunity after inoculation, has been criticised on the one hand and stanchly supported on the other. Professor Metschnikoff—whose researches upon the behavior of the cells of Daphnia to the spore disease that attacks this entomostracous organism formed the basis of this doctrine—returns to the subject in an article upon the "strife between cells and the cocci of erysipelas." He declares that Fehleisen's observations upon the minute anatomy of cutaneous erysipelas harmonize with the theory of phagocytes (*The Lancet*). The spreading margin of an erysipelatous patch can be differentiated into three zones: a peripheral, in which the lymphatic spaces are filled with the streptococcus in a state of active growth; a middle, exhibiting inflammatory reaction in abundance of leucocytes between the masses of cocci; and an internal, in which cocci are conspicuous by their absence. Metschnikoff examined several cases: some fatal; others, which recovered, with the view of testing the truth of his surmise that recovery from erysipelas is due to the destruction of the microbe by the phagocyte. In the one case of fatal gangrenous erysipelas he found a few disintegrating leucocytes and an abundance of cocci; in the other, where recovery took place, leucocytes were seen filled with cocci or their débris; and transitional states could be traced between these extremes in specimens derived from other cases. The inference he gathers is that in the fatal cases the streptococci gain the mastery from defective inflammatory reaction. Besides the small free leucocyte, he assigns similar properties to larger cells derived from the fixed connective-tissue elements in the subcutaneous tissue. The former he terms *microphagi*, the latter *macrophagi*, and he notes an important difference in the function of these two elements. In the subcutaneous tissue in erysipelas he finds macrophagi which do not consume the micrococci. That office is confined to the microphagi, whereas it appears to be the duty of the larger elements to consume the débris of the dead and dying leucocytes. The macrophagi therefore perform the useful function of clearing the battle-field of the slain leucocytes; and they therefore increase in size and number in proportion as the strife between the microphagi and streptococci diminishes. It reads almost like a romance, this account of the mimic warfare carried on to the death between the invading microbe and the defending leucocyte; and yet the phenomena of local infection, inflammatory reaction, resolution and absorption of the inflammatory products can all be expressed in the terms of streptococcus, microphage, and macrophage. Other factors, it is admitted, may be at work—such as pyrexia—but Professor Metschnikoff holds to the foregoing as a most probable explanation of the local phenomena. In asserting this, he has had to meet the arguments adduced by Baumgarten and others, especially with reference to the fact that in many infective diseases bacteria are found within leucocytes without any variation from the fatality exhibited, and also the fact that experimental injections into the blood of bacteria do not lead to the consumption of the latter by phagocytes. However, he meets these and other objections, and declares that Cohnheim's dictum, "no inflammation without blood-vessels," must be changed into "no inflammation without phagocytes." The doctrine is attractive, and is deserving of further study; but it cannot be said to be established, or as yet far removed from the stage of probability.

An Enormous Calculus.—Dr. Colson, of Aden, reports the following case in *The Lancet*: A Bedouin Arab who had come eight days' journey to Hodeedah, and thence by sea to Aden, presented himself at the Civil Hospital for treatment for calculus of the bladder. On February 1st, when on the operating-table, the stone was carefully examined with the sound and per rectum. Having come to the conclusion that the stone was a very large one, he determined on the supra-pubic operation. The bladder was injected with twenty ounces of warm water, which raised it well above the pubes. An incision about three inches in length was made vertically above the pubes, and the parts carefully dissected down until the veins above the bladder were exposed. While separating these with a director, it passed through into the bladder, which appeared soft and friable. The finger was immediately introduced through the opening, and an enormous stone was found to occupy the cavity of the organ. To extract this the original incision had to be much enlarged, and with great difficulty the stone was removed. This was found to weigh nine and a half ounces avoirdupois, and measured seven and a half inches in its horizontal and eight and a half inches in its vertical circumference. A large catheter was fastened in the bladder per urethram, and the wound in the skin closed and dressed antiseptically. The man recovered well from the immediate effects of the operation, and was doing well also in the evening. But he died suddenly on the following morning.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, June 11, 1887.

CRIME AND MONOMANIACAL INFATUATION.

THE Connecticut Legislature has recently enacted a law for the prolonged confinement of incorrigible criminals, *i.e.*, persons who have been sentenced three times for a period of not less than two years. The law provides that at the expiration of the third sentence the criminal shall be detained in prison for twenty-five years. This is a wise law, and fully in accordance with the modern teachings of alienists and penologists.

In an article in the *Journal of Nervous and Mental Diseases* for May, 1887, Dr. William Duffield Robinson gives an interesting account of this "crime-class," to which the law just referred to applies. He states that the major part of State-prison offences are the acts of men born to crime. These people very seldom reform. They have as little control over their inclinations to violate law, as has the confirmed inebriate over his desire to drink. They are not intemperate, as a class, but are given to venery. Their intelligence varies greatly, but as a rule they possess great cunning and adroitness, though ignorant and illiterate. With this class crime, says Dr. Robinson, is unquestionably "a monomaniacal infatuation."

These congenital criminals often show physical imperfections of various kinds. The shape of the cranium and the arrangement of the convolutions are, according to some, very characteristic. Twenty per cent. at the age of forty years have had syphilis; ten per cent. develop insanity some time before their death, as against 0.2 per cent. among the whole population. There is a startling proportion of tubercular disease in their families. Epilepsy and other nervous diseases are also very common. About six per cent. of the convict population shows a strong inherited tendency to insanity; over seventeen per cent. shows family histories of crime, and where two or more families are convicts, they will show a *penchant* for a peculiar class of crimes.

Among 3,500 convicts received into the Eastern State Penitentiary of Pennsylvania, in the past five years, 245 were insane, 40 had insanity developed during confinement, while 20 were guilty of simulating insanity.

There are thus facts enough to convince any intelligent person that we do have a crime-class, that its members are born with impulses to commit crime, which impulses are as uncontrollable as those of the epileptic or the insane. We do not forget that many persons, apparently congenital criminals, are really criminal through education and association. It remains to be shown that the children of the crime-class, if put under perfectly good surroundings, would not develop into useful citizens. Making all due allowances, however, there does exist a crime-class not entirely responsible; and the best way to deal with it is to isolate and stamp it out, as the Connecticut Legislature proposes to do.

MEDICAL SLANG.

THE microscopist in this city who speaks of his slides as "toboggans" is only following a very prevalent custom among many of our younger medical men, of using slang phrases in place of the dignified terminology of pure science. This practice of substituting highly idiomatic Saxon or time-saving abbreviations for the pure phraseology of the text-book, has reached such extent that it needs a passing notice.

Illustrations of it are plentiful. Thus, one finds that sufferers from the most terrible of specific disorders are lightly referred to as having "syph," and that pregnant monosyllable is also applied to the whole science of syphilography. Students in pathology find that they are taking a course in the "bug-class" of the distinguished bacteriologist who is only a "bug-man." By the same rules of condensation eminent specialists in laryngology, ophthalmology, dermatology, etc., are only "throat-" or "nose-men," "eye-men," and "skin-men." Gynecologists devote themselves to a specialty which, in the iconoclastic vernacular of to-day is referred to as "woman's."

It would be somewhat horrifying for the laity to learn of all the various apparently unsympathetic synonyms applied in hospitals to the sad *exitus lethalis* of the patients. To the poet and the preacher the "spirit takes its flight," but to the *interne* the patient has simply "pegged out," and the question is not as to the destination of his soul, but the disposition of his body.

It would be indelicate to say what term is applied to the classes in that most useful branch of knowledge, urinary analysis, and it would be ungracious to quote the pure Saxon by which the enthusiasts in laparotomy are designated.

Medical slang is a thing which is inevitable, and its use is not altogether to be deprecated. There is a deal of virility and meaning in many slang expressions; and we only need express the desire that these be neither excessively multiplied nor indelicately used.

DRUGGED BEER.

THERE is a growing belief among sanitarians that salicylic acid is being used more and more extensively in the preservation of canned foods, milk, wine, beer, and other articles. To such an extent was this done in Paris that the French government has already twice taken action upon the matter. Dr. E. H. Bartley, Chemist to the Brooklyn Health Department, has recently called attention to this matter. He states that in 1885 the chief adulterations which he found in beer were yeast and bicarbonate of soda. Lately he has examined several different kinds of bottled beer sold in Brooklyn, the list including some of the Western beers. He has found salicylic acid in

them. The amount of this acid required to preserve beer is about twelve to fifteen grains per gallon. Salicylic acid, if taken continuously, tends to injure digestion and irritate the kidneys.

THE HEART-BEAT AND THE RESPIRATORY CHANGES.

It is an established fact in physics that if a liquid containing a gas be placed in a vacuum only a small part of the gas escapes, unless the liquid be subjected to a blow just before the exhaustion process is commenced. Professor Von Fleische, of Vienna, has applied this fact in a study of the relation between the heart-beat and the respiratory changes in the lungs. He thinks that the blood, in the pulmonary arteries containing the carbonic-acid gas in solution, is jarred by the motion of the heart, and in this way assistance is given in setting free the CO_2. It is quite true, as Von Fleische claims, that the physics of the process by which this gas passes from the blood-serum to the air in the alveoli has been obscure, because there is little difference between the pressure in these spaces and in the blood. Von Fleische's theory affords a plausible explanation. If it is true, then cyanosis from weak heart is due, in a measure at least, to the feeble impact of the heart-muscle, and externally applied blows ought to relieve dyspnœa. The facts of comparative anatomy are claimed in support of the view just described.

THE TREATMENT OF TUBERCULOSIS OF THE LARYNX.

In the treatment of tuberculous ulcerations of the larynx Dr. A. Rosenberg, of Berlin, applies a five to twenty per cent. oily solution of menthol to the affected parts. The solution is sprayed into the larynx, at first once or twice daily, then less often. The effect is said to be "extraordinarily favorable." Menthol, in proportion of 1 to 33,000, inhibits life in anthrax bacilli, and presumably in tubercle bacilli. It is on the ground of its anæsthetic and antiseptic properties that the agent is used.

Dr. V. Brunn, of Lippspringe, has been using twenty to forty per cent. solutions of lactic acid in laryngeal tuberculosis, according to the recommendations of H. Krause. He has obtained excellent results with this, and speaks of it as "a true panacea." But in some very sensitive patients the application is too irritating, and provokes great pain, coughing, and feelings of suffocation. Dr. Brunn therefore tried a twenty per cent. oily solution of menthol, according to the method of Rosenberg. He confirms the views of that observer as to the utility of the applications. He now employs the lactic acid in persons of strong build and lymphatic temperament, the menthol in those of a weak and irritable constitution.

Lactic acid and menthol seem likely to play the leading part which iodoform took in laryngeal tuberculosis some years ago.

HOSPITAL AT DAMASCUS.—Dr. Macinnon, of the Scottish Medical Mission, has recently opened a hospital for poor patients at Damascus. The fanaticism of the Mohammedan population has forced the government to close it, and Sir W. White is now making representations to the Porte to grant the hospital its protection.

News of the Week.

THE ILLNESS OF PROFESSOR BILLROTH.—A recent despatch from Vienna says: "All classes of the Vienna population are deeply moved by the dangerous illness of Dr. Billroth, a surgeon of world-wide reputation Hundreds of students and others stand before his house to hear the latest news. Dr. Billroth is suffering from fatty degeneration of the heart, together with inflammation of the lungs.

THE SOCIETY PAPERS OF LONDON announce that "Dr Harrison, of America," is lecturing successfully "to men only" at Prince's Hall, London. Dr. Harrison is spoken of as "highly intelligent and racy"—to men only, we presume.

A DOCTOR'S KINDNESS TO THE CLERGY.—A clergyman writes to *The Lancet* that the late Dr. Wilson Fox was in the habit of placing his beautiful house at Rydal at the disposal of the Bishop of Bedford for the use of the invalided East End clergy and their families during the summer months. The liberality, kindness, and delicacy with which this was done will be understood by all who knew him.

THE WEST VIRGINIA STATE MEDICAL SOCIETY will hold its twentieth annual session at White Sulphur Springs, W. Va., July 13, 14, and 15, 1887. The Secretary is J. L. Fullerton, M.D., of Charleston, W. Va.

THE DEATH OF DR. CARL FRIEDLÄNDER, of Berlin, is announced. He was well known for his contributions to pathological anatomy, and was editor of the *Fortschritte der Medicin*.

A SCHOOL OF PHARMACY is to be opened in connection with Cornell University during the coming fall. Women and men are to be admitted.

THE CAUSE OF GROUSE-DISEASE.—M. Pasteur is to make an investigation into the cause of grouse-disease.

SPECIALISM IN EXCELSIS.—*The Lancet* grows facetious in the following manner. Under the title of "Specialism in Excelsis" it says: "We have received a programme of the first annual meeting of the 'Association of Genito-urinary Surgeons,' which is being held this week at the Laurel House, Lakewood, N. J. The establishment of this association has been attended with so much success, and commends itself so thoroughly to the more enlightened members of the profession, that many similar ones are shortly to be inaugurated. Among those more immediately to be promoted are associations of 'Umbilicologists,' of 'Rhinologists,' of 'Tenotomists,' of 'Depilatory Surgeons,' and of 'Skin-grafters.' The only reason we can perceive why this list should not be indefinitely extended is that surgery, as an art, would, by such differentiation, speedily be resolved into its constituent elements, and its professors broken up into repellant groups of solemn deliberators on the utility and beauty of the segregation of parts."

FOR THE ARREST OF CANCER.—Dr. Peter Hood (*The Lancet*) recommends a three months' course of carbonate of lime for the arrest of cancerous growths. Dr. Hood first called attention to this twenty years ago. Further experience leads him to recommend the plan again.

Reports of Societies.

American Medical Association.

THIRTY-EIGHTH ANNUAL MEETING.

Held in Chicago, Ill., June 7, 8, 9, *and* 10, 1887.

[By Telegraph to The Medical Record.]

TUESDAY, JUNE 7TH—FIRST DAY.

The Association met in Central Music Hall, and was called to order at eleven o'clock by the Chairman of the Committee of Arrangements, CHARLES GILMAN SMITH, of Chicago. Prayer was offered by REV. S. J. MCPHERSON, D.D., and the address of welcome was made by Mayor JOHN A. ROCHE.

The ex-Presidents were invited to take seats upon the platform, and N. S. Davis, of Chicago; T. G. Richardson, of New Orleans; J. M. Toner, of Washington, and William Brodie, of Detroit, responded to the invitation.

DR. P. H. MILLARD, of Stillwater, Minn., First Vice-President, being in the Chair,

DR. SMITH then introduced the President, DR. E. H. GREGORY, of St. Louis, who delivered the

ANNUAL ADDRESS,

in which he congratulated the Association on the auspicious opening of its annual meeting, and expressed his high appreciation of the honor bestowed upon him by elevating him to the presidency. He then said that force and matter make up the universe; that force implies antagonism; that antagonism perpetuates motion; that a living cell is the embodiment of nature; that cell-antagonism is life, and that a model organism in equilibrium is health. The comprehensive title of his paper was "Cell-Antagonism," which forms the foundation of symptomatology and pathology, and, conjoined with the cell-changes constituting the basis of pathological anatomy, presses at once the universe of life, disease being but one of the multitudinous phases of life.

Cell-antagonism constitutes the essential of pathology. Inflammation, the keystone of medical science, is only to be explained on the theory of cell-antagonism—a struggle between irritant bodies and white blood-cells. Cells live on themselves, by themselves, and for the whole body. The giant-cells are formed by the uniting of the budding processes from the amœboid mass of protoplasm. These giant masses of protoplasm appear in lupus and tubercle, and in their substance the bacillus is found. With the observations before us concerning cell-antagonism inflammation presents a new aspect. He then outlined the view that there is a struggle between encocytes and bacteria, and that when the microbes prevail suppuration takes place. From this could be seen the close relation between Pasteur's work of preventive inoculation and Lister's equally important work in devising methods by which the microbes can be rendered harmless. Some time was devoted to the consideration of the question, whether or not a cell can enter upon a life of independence, and from this he passed to Cohnheim's theory of the etiology of tumors, namely, persistence of germinal rudiments. Emancipation of cells seems to be almost out of the question.

The President then referred in fitting words to the death of W. O. Baldwin, ex-President of the Association. The address closed with a reference to the coming International Medical Congress, the success of which is assured. He urged the Association to welcome all to the great gathering.

The address was referred to the Committee on Publication, and a vote of thanks given to the President.

DR. A. NELSON BELL, of New York, offered under the head of "Reports of Special Committees" the

REPORT OF THE COMMITTEE ON IMMIGRATION,

which by accident failed to reach the Association last year. The report was read and the committee presented the following resolution, which was adopted:

Resolved, That the Secretary of the Association be and is hereby directed to transmit copies of this report to the Secretary of the Treasury of the United States, and to both the Senate and House Committees on Commerce, and urge upon them such action, through Congress or otherwise, that will secure better protection of the lives and health of immigrants coming to the United States, and against the reception of dependent persons.

DR. D. J. ROBERTS, of Tennessee, introduced a wordy preamble and a set of resolutions condemning an editorial on the American Medical Association that appeared in the Chicago *Times*. He regarded the Times as sadly out of joint, and wished to deny that

CHICAGO IS UNFAVORABLE FOR HARMONIOUS MEDICAL ACTION,

and protested against the statement that the orthodox medical men of this region are beyond doubt the most bigoted and intolerant in the nation.

DR. DUDLEY S. REYNOLDS, of New York, moved the adoption of the resolutions.

DR. EUGENE GRISCOM, of North Carolina, moved that they be laid upon the table, which was carried by 133 ayes and 89 nays.

On motion by DR. WILLIAM BRODIE, of Detroit, the amendment to the by-laws providing for a section in dermatology and venereal diseases was taken from the table.

On motion by DR. G. H. ROHE, of Baltimore, the amendment was amended so as to read dermatology and syphilography and then adopted.

DR. J. MCF. GASTON, of Atlanta, Chairman of the Committee to Memorialize Congress with reference to

INOCULATION FOR YELLOW FEVER,

presented the report, which was referred to the Section on State Medicine.

At the meeting of the

ASSOCIATION OF AMERICAN MEDICAL EDITORS

William Porter, of St. Louis, was elected president; Thomas J. McIlvaine, of Peoria, vice-president, and W. C. Wile, of Philadelphia, secretary and treasurer.

The Entertainment Committee made generous arrangements for demonstrating the hospitality of the city.

WEDNESDAY, JUNE 8TH—SECOND DAY.

The Association was called to order by the President, and prayer was offered by REV. MR. GUNSAULUS, of Plymouth Church.

DR. J. M. TONER, of Washington, Chairman of the Board of Trustees for the

PUBLICATION OF THE JOURNAL OF THE ASSOCIATION,

read the annual report, which included the report of the editor, N. S. DAVIS, of Chicago, who has consented to remain the managing editor of the *Journal* for another year. The report stated that the general success of the *Journal* had been more gratifying during the year than could have been expected. The report of the editor showed that there had been a net increase of subscribers of 104 during the year; that the total editorial expense, including society reports, correspondence, etc., had been $2,758.95; that the total expense of publishing the *Journal* had been $15,920.96; that the total cash value of the property on hand is $1,058.56. The net increase on the subscription list included new names that had been added, balanced by those which had been dropped for non-payment of dues. The editor recommended more permanent arrangements affecting publication and printing than now exist.

The report was accepted and adopted.

DR. ROBERTS, of Tennessee, asked permission to withdraw his resolutions, which were tabled yesterday, because the Chicago *Times* had made satisfactory acknow

ledgment regarding its unwarranted reflection on the regular medical profession of this city and portion of the country. His request was granted.

Dr. N. S. Davis, of Chicago, chairman of the

SPECIAL COMMITTEE ON CHANGES IN THE PLAN OF ORGANIZATION AND BY-LAWS OF THE ASSOCIATION,

made an elaborate report, in which were reviewed the geographical and medical extent of our country; the plan of organization and operation of the British Medical Association; the present relation which exists between the American Medical Association and the State and county medical societies and the national and local organizations. The Committee reached the conclusion, after a most careful study of the development of medical organizations at home and abroad, that it could not recommend any radical changes in the existing plan of organization of this Association.

There were, however, certain defects in the present plan and its by-laws that could be remedied with advantage, and the Committee recommended that the method of admission to membership by application be so amended as to include such members of State, county, and district medical societies entitled to representation in this body as shall make application in writing to the treasurer, and accompany said application with a certificate of good standing signed by the president and secretary of the society of which they are members, together with the amount of the fee for membership, five dollars. Such members shall have their names entered upon the roll and be entitled to all the privileges of permanent members, and shall retain their membership on the same terms as though they had obtained permanent membership by serving as delegates. In the fifth section of the constitution, the Committee recommended that paragraphs one and three be stricken out, and that in place of the first paragraph there be substituted the following important provision: The general committee on council shall be composed of two members from State and Territorial medical societies represented by delegates to this Association, and from the medical departments of the Army, Navy, and Marine Hospital Service. They shall be chosen by the members registering and present at the annual meeting, these organizations acting separately. There were further provisions making the term of office two years. This general committee shall meet on the day preceding that fixed for the meeting of the Association, and as often during that week as may be necessary; and for the purpose of nominating on the third day of each annual meeting all the officers, none of whom shall be members of their own body—he judicial council, the board of trustees for the *Journal*, etc., and all for election by the Association. This committee shall also recommend a place and time for the annual meeting, consider and report on all subjects which may be referred to it by the Association, and particularly all propositions introduced which involve appropriations of money. These recommendations, the chairman said, simply put in due form and proper place the regulations that had actually been in operation for the past four years under resolutions adopted at the annual meetings in 1882 and 1883.

As to the by-laws, the Committee recommended that they be so amended that the chairmen of sections shall be required to prepare addresses on the recent advancements in their departments, to be read before the sections on the first day of the annual meetings; such addresses not to occupy more than forty minutes in their delivery. This method is now practised in the British Medical Association. An additional by-law was recommended providing that three members of the profession shall be elected by the Association to deliver addresses in the general sessions of the Association at the next ensuing annual meeting, and that each address shall not occupy more than one hour in its delivery.

All these changes recommended had for their object the better adjustment and more practical development of the systematic general organization of the medical profession in our country, and these principles of equality and just representation in direct accord with the habits of our people and the methods of our institutions.

The report did not give rise to discussion other than that relating to the question whether or not the proposed amendments could be adopted at this meeting, or must lie over for one year.

Dr. A. N. Bell, of New York, moved that it was the sense of the Association that these proposed amendments hap been practically considered according to the requirements of the constitution for one year.

Carried—ayes, 272; nays, 232.

Motions, counter-motions, amendments, previous questions, and points of order were offered in profusion, but the President decided that the report of the committee had been accepted and adopted, and that this adapted the proposed amendments to the constitution and by-laws.

The Secretary, W. B. Atkinson, of Philadelphia, announced the Committee on Nominations: Alabama, W. C. Cross; Arkansas, D. C. Ewing; California, J. W. Robertson; Colorado, P. Brumund; Connecticut, W. H. Whittimore; Dakota, E. M. Dow; District of Columbia, J. M. Toner; Florida, M. B. Phillips; Georgia, A. G. Whitehead; Illinois, E. P. Cooke; Indiana, T. B. Harvie; Iowa, W. W. Watson; Kansas, W. L. Schen; Kentucky, Dudley S. Reynolds; Louisiana, T. G. Richardson; Maine, D. E. Marston; Maryland, T. B. Evans; Massachusetts, E.W. Cushing; Michigan, William Brodie; Minnesota, J. A. McGaughey; Mississippi, T. R. Trotter; Missouri, J. M. Allen; Nebraska, W. M. Knapp; North Carolina, Eugene Griscom; New Hampshire, J. W. Parsons; New Jersey, Lott Southard; New Mexico, Russell Bailey; New York, Darwin Colvin; Ohio, X. C. Scott; Pennsylvania, E. A. Wood; Rhode Island, W. J. Burge; South Carolina, T. Legare; Tennessee, J. B. Murfrie; Texas, R. W. Park; Vermont, S. H. Griswold; Virginia, L. M. Nash; Wisconsin, J. K. Bartlett; United States Navy, D. Bloodgood; United States Marine Hospital Service, Charles B. Goldsborough.

The following resolution, sent by the American Pharmaceutical Association, was read and adopted:

Resolved, That this association solicits the aid and cooperation of the American Medical Association in promoting the prescribing of official medicines only, or such preparations as have published formulas, in preference to others.

THE ADDRESS OF THE CHAIRMAN OF THE SECTION IN THE PRACTICE OF MEDICINE

was delivered by Dr. John S. Lynch, of Baltimore. The chairman first directed attention to the use of antipyrin, which he had found to be uniformly useful in all febrile diseases. After a brief reference to digitalin, he took up the subject of pulmonary phthisis, and Koch's theory of its dependence upon a bacillus. If contagious or infectious, it differs from all other diseases belonging to this class. While he denied that the bacillus is the sole or frequent cause of this disease, it may have some pathological influence in the development of conditions that favor the development of phthisis, especially caseous degeneration. The danger from bad hygienic surroundings he regarded as greater than that from direct contagion. As to treatment, he could report nothing in favor of Bergeon's method of rectal injections of sulphuretted hydrogen-gas. He believed there was nothing in this treatment except money for the sharks and charlatans, and that antiseptic treatment must remain impossible. Any germicide which can destroy the microbes must kill the patient. The address had one merit, namely, that of brevity.

There was no address in Surgery.

The Association then adjourned to meet on Thursday at 10 A.M.

THURSDAY, JUNE 9TH—THIRD DAY.

The Association was called to order by THE PRESIDENT, and prayer was offered by REV. JOHN A. BARROWS, D.D.

A telegram from the Ontario Medical Association, sending congratulations, was received, and was responded to by sending sympathy and good-fellowship from the American Medical Association.

DR. BRODIE, of Detroit, Chairman of the Committee on

NOMINATIONS,

made the following report:

President—A. Y. P. Garnet, of Washington.

First Vice-President—Duncan Eve, Nashville, Tenn.

Second Vice-President—Darwin Calvin, Clyde, N. Y.

Third Vice-President—Charles J. O. Hagan, North Carolina.

Fourth Vice-President—A. Stedman, Colorado.

Librarian—C. H. A. Kleinschmidt, Washington.

Treasurer—R. J. Dunglison, Philadelphia.

Permanent Secretary—W. B. Atkinson, Philadelphia.

Assistant Secretary—Joseph Ransohoff, Cincinnati.

Trustees of the Journal—Leartus Connor, Detroit; E. O. Shakespeare, Philadelphia; W. T. Briggs, Tennessee.

Judicial Council—J. H. Murphy, St. Paul; J. M. Toner, Washington; J. K. Bartlett, Milwaukee; A. B. Sloane, Missouri; X. C. Scott, Cleveland; A. W. McLuer, Iowa; D. W. Stormont, Kansas; J. H. Hibberd, Indiana.

Committee on Necrology—J. M. Toner, Chairman.

Committee on State Medicine—R. G. Jennings, Little Rock, Chairman.

THE NEXT ANNUAL MEETING

is to be held at Cincinnati on the second Tuesday in May, 1888. Chairman of Committee of Arrangements, Dr. W. W. Dawson, of Cincinnati, with power to fill the Committee by appointment.

OFFICERS ELECTED BY THE SECTIONS.

Surgery—Donald McLean, Ann Arbor, Chairman; B. A. Watson, Jersey City, N. J., Secretary.

Medicine—A. B. Palmer, Ann Arbor, Chairman; N. S Davis, Jr., Chicago, Secretary.

State Medicine—H. B. Baker, Lansing, Mich., Chairman; S. T. Armstrong, Tennessee, Secretary.

Children—F. E. Waxham, Chicago, Chairman; W. B. Lawrence, Batesville, Ark., Secretary.

Dental and Oral Surgery—J. Tafft, Cincinnati, Chairman; E. S. Talbot, Chicago, Secretary.

Ophthalmology and Otology—F. E. Hotz, Chicago, Chairman; H. H. Jackson, Philadelphia, Secretary.

Dermatology and Syphilography—L. Duncan Bulkley, New York, Chairman; T. Fayette Dunlap, Secretary.

Medical Jurisprudence—E. M. Reid, Baltimore, Chairman; Dr. Belt, Boston, Secretary.

A question arising concerning the

AMENDMENTS TO THE CONSTITUTION AND BY-LAWS

acted upon yesterday, DR. ROBERTS, of Tennessee, moved that further action in accordance with them be postponed until next year; which was amended by DR. N. S. DAVIS, of Chicago, that the proposed amendments to the constitution be not adopted, but lie upon the table subject to ratification in proper order at the opening of the next annual meeting, and then unanimously adopted.

DR. G. H. ROHE, of Baltimore, in the absence of Dr. A. L. Gihon, Chairman, read the report of the

COMMITTEE ON A MONUMENT TO BENJAMIN RUSH,

which showed that $389 had been received. In connection with the report was read a letter from Mr. Hack Tuke, of England, wishing the project success. The report was referred to an Auditing Committee, consisting of Eugene Grissom, of North Carolina; A. Garcelon, Maine, and A. B. Palmer, Ann Arbor, which subsequently reported that the accounts had been found to be correct.

DR. JOHN MORRIS, of Baltimore, in the absence of Dr. J. M. Keller, of Hot Springs, Ark., read the report of the

SPECIAL COMMITTEE ON CREMATION,

which closed with the following resolution:

Resolved, That it is the judgment of this Association that burial of persons dying of zymotic diseases should be placed by law under the control of health authorities.

On motion by Dr. Morris the report was referred to the Section on State Medicine.

DR. J. MCF. GASTON, of Atlanta, Ga., introduced the following resolution, which was opposed by Dr. G. H. Rohe, of Baltimore, but was adopted:

Resolved, That it is the sense of this Association that it is desirable that two other members of the medical profession be associated with the Committee on Inoculation of Yellow Fever already appointed, and that a committee of three be appointed to communicate this action to President Cleveland.

DR. F. M. JOHNSON, of Kansas City, Mo., delivered the

ADDRESS OF THE CHAIRMAN OF THE SECTION ON OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

The past year has given but few remarkable discoveries in either obstetrics or gynecology. Reference was then made to tubal diseases, and the ease and lack of danger with which the operation can be performed, diagnosis being made certain. The practice of leaving a portion of an ovary is of questionable propriety. Electricity has become well established as a therapeutical agent in gynecology. Reference was also made to cocaine as a local anæsthetic, to the use of nitrate of silver for early discovered lacerations of the cervix, and also to Alexander's operation, which he believed would not stand the test of time. In obstetrics, modified Cæsarean section was probably destined to succeed the use of forceps or version in certain cases.

Extended allusion was made to A. F. A. King's paper on the renal troubles and eclampsia of pregnancy and labor, and from this the Chairman passed to the use of ergot and the management of the placenta. A diversity of opinion exists as to the utility of uterine and vaginal injections during the puerperal period, but the application of antiseptic principles in obstetrics was no longer a question, for the decided reduction of mortality in hospitals was an unanswerable argument in their favor. Better success would be secured in the general use of antiseptics if a broader view of the subject were taken, and more attention paid to the principles of treatment, with less adherence to doctors' methods of carrying it out than has heretofore obtained.

THE ADDRESS OF THE CHAIRMAN OF THE SECTION ON STATE MEDICINE

was given by DR. G. H. ROHE, of Baltimore.

The record for State medicine during the past year is a creditable one. As to cholera, the danger of invasion of this country is at present greater than at any time within the past three years. Reference was then made to yellow fever inoculation, the method now being subjected to an official investigation, authorized by the Government. Diligent search has been made for the specific organism supposed to be the infective agent in vaccine virus, but without definite success. The results obtained are not entirely negative, however, and one may cherish the hope that a solution of this problem will soon be reached. The relation of a peculiar disease in cows to scarlet fever, and the discovery of a specific microbe in the blood in the latter disease, have attracted much attention.

The restriction of scarlet fever will doubtless be more thoroughly effected so soon as physicians are convinced of its bacterial nature and clearly comprehend its mode of transmission. Measures for the restriction of pulmonary tuberculosis were adverted to. Tuberculous patients should not be treated in the same hospital wards with non-tuberculous individuals, and prompt disinfection of the sputa and other discharges should be practised, in order to diminish opportunities for infection. General sanitary measures should, however, not be neglected in the warfare upon the bacillus. There is danger that a too exclusive attention to the microbian factors of disease will narrow our views of epidemiology and preventive medicine.

It seems to be established that the micro-organism discovered in the intestinal lesions and discharges in typhoid fever is the cause of this disease. The fact that this microbe may preserve its vitality for a considerable time in water and ice has been shown by Bolton, Wolff-Hügel, Prudden, and others. This, together with the well-known history of outbreaks of this disease, undoubtedly depending upon pollution of drinking-water, should make prompt measures of disinfection imperative in every case. The physician fails in his duty who neglects measures for the thorough destruction of the typhoid infection existing in the intestinal discharges. The importance of disinfection of bedding, clothing, and other personal and household articles in contagious diseases, demands that health authorities should have under their control establishments where disinfection can be carried out on a large scale and at public expense. Quarantine—a word which for more than five centuries has been synonymous with barbarism—is becoming, under methods, a safeguard to the public against infection, and an advantage instead of obstruction to commerce.

Cremation of garbage seems to be the best method yet devised for the inoffensive destruction or final disposal of solid city wastes. The irrigation system of sewage disposal has steadily won favor.

Professor Vaughan's discovery of a very poisonous ptomaine in cheese, ice-cream, and milk undergoing certain chemical changes, has been confirmed by a number of investigators in various parts of the country. Analyses of food and drugs, made during the year in Massachusetts and New York, show the wide extent to which adulteration is practised, and how the people are defrauded. Authority and means should be given to the health authorities to protect the public from these frauds, many of which are a source of danger to life and health.

Statistics collected by the speaker show that five-sixths of the inhabitants of cities in this country have no facilities for bathing, except such as are afforded by a pail and sponge, or an easily accessible river, lake, or other body of water. The establishment of public baths is urgently recommended, both as a sanitary as well as moral measure. Public baths should be open the year round, and not alone during the summer.

A number of instances are grouped together showing how the enforcement of appropriate sanitary measures has saved life. In Michigan the saving of life from one disease (scarlet fever) has amounted, during the last eleven years, to 3,718, or three hundred and thirty-nine per year. In 1886 appropriate sanitary measures saved the lives of 298 persons who would have died of diphtheria if such measures had not been enforced. In England and Wales the average annual saving of life due to sanitary measures has amounted, in the five years ending 1885, to 62,000. While all advances in sanitary administration have doubtless contributed to produce these good results, the main influence is to be attributed to three factors. These are: Compulsory notification of infectious disease, prompt and effective isolation of the sick and infected, and thorough disinfection of all infected articles and sources of infection. These must be the watchwords of the practical sanitarian of the future.

Dr. G. S. Knox, of Chicago, presented the

ADDRESS OF THE CHAIRMAN OF THE SECTION ON DISEASES OF CHILDREN.

The address was read in abstract, and had for its subject diatheses in diseases of children. The speaker brought out concisely the relation existing between diseases in children and the tubercular, syphilitic, and rheumatic diatheses.

The treasurer's report showed a balance in the treasury of $1,403.77.

The librarian's report was read, and placed on file.

THE COMMITTEE ON FINANCE OF THE INTERNATIONAL MEDICAL CONGRESS

asked for an appropriation of money. After stirring speeches, in which were set forth the pressing and urgent financial needs of the Congress, one thousand dollars were appropriated, and it was earnestly hoped that every member of the Association would make immediate and liberal contributions, besides the amount required for membership.

Dr. N. S. Davis, of Chicago, offered the following resolutions, which were made the special order for Friday at the conclusion of the address:

First, That regular graduates of dental and oral schools and colleges which required of their students a standard of preliminary or general education to the term of professional study be recognized as members of the regular profession of medicine and eligible to membership in this Association on the same conditions and subject to the same regulations as other members.

Second, That the Committee of Arrangements are hereafter directed, at each annual meeting of this Association, to so arrange the programme regarding entertainments and receptions that the evening of the third day be reserved for the regular annual dinner, under such regulations that the members may dine with or without wine, according to choice, and pay only for what they elect to have furnished, and that that be the entire cost of the dinner, leaving no part to be paid either by the local profession or the treasurer of the Association.

Dr. Burge, of Brooklyn, introduced resolutions, which were adopted, and which directed the Committee of Arrangements hereafter to adopt some efficient means for preventing conversation and noise in the hall while the general sessions of the Association are had.

The Association then adjourned, to meet on Friday at 10 A.M.

Friday, June 10th—Fourth Day.

The Association was called to order by The President, and prayer was offered by the Rev. W. H. Vibbert, D.D.

The address of the Chairman of the Section on Dental and Oral Surgery was delivered by Dr. J. S. Marshall, of Chicago.

Dr. J. M. Quimby, of Jersey City, N. J., read the

ADDRESS OF THE CHAIRMAN OF THE SECTION ON MEDICAL JURISPRUDENCE.

He first gave an outline of the history of medical jurisprudence from the early periods of Hebrew, Greek, and Roman antiquity. The only medical laws of which we have any distinct account during the Dark Ages were for the prevention of infectious diseases at Venice, A.D. 1127. But special quarantine regulations, scarcely worthy of the prefix medical, were not established until more than two centuries later. The cloud began to lift, in the early part of the sixteenth century, under the reign of Charles the Fifth. The Criminal Code of the German Empire, enacted in 1532, contains the first appreciation of rational medicine in union with law. This justly celebrated code requires that physicians shall be called by the courts in all cases where death has been the result of violent means, whether accidental or criminal. The office of

coroner is as ancient as A.D. 905, and originated among the Saxons. The functions of the coroner in England and France were then described, and it was seen that more weight appeared to have been attached to the importance of medical testimony in coroners' cases in France two centuries ago than now obtains in the United States.

Medical jurisprudence was first taught in the medical schools in Germany in the latter part of the eighteenth century. But the first professorships were created in France in 1792, and in 1803 the University of Edinburgh followed the example. No similar chair was established in England, however, until sixteen years after. It was taught in a course of lectures in Columbia College, New York, by James S. Stringham, professor of chemistry, in 1817, who was succeeded by John W. Francis.

The preservation of fœtal and infantile life was then considered, and he suggested that a special committee be appointed by the Association to report at the next annual meeting upon the criminality of fœticide and such measures as may be commended for legislative action for its prevention and punishment. Attention was directed to the duties exercised commonly by coroners and the means of improving medical police in regard to immigration, with special reference to the detection and prohibition of chronic invalids and insane persons.

The address closed with a special reference to the medical jurisprudence of drunkenness.

Dr. J. M. Toner, of Washington, presented the

REPORT OF THE COMMITTEE ON NEUROLOGY.

Dr. N. S. Davis, of Chicago, reported from the Standing Committee on Meteorological Conditions and their relations to the prevalence of disease; also concerning the collective investigation of disease in co-operation with the committee of the British Medical Association.

The customary

RESOLUTIONS OF THANKS

to all who had contributed to the success and pleasure of the meeting, to the citizens and the profession of Chicago, to the railroads which had given reduced rates, to the Chairman of the Transportation Committee, and to Assistant Secretary Listo H. Montgomery, of Chicago, to the various committees and their chairmen, and to the President, were adopted.

A telegram from Dr. Garnett was received, acknowledging the high honor conferred upon him in electing him President.

The Association then adjourned.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

Second Annual Meeting, held at Washington, D. C., June 2 and 3, 1887.

THURSDAY, JUNE 2D—FIRST DAY—MORNING SESSION.

The meeting was called to order at ten o'clock by the President, Dr. S. Weir Mitchell, of Philadelphia, who delivered a brief address. He reported the death of three members—Dr. Thomas F. Rochester, of Buffalo; Dr. Thomas A. McBride, of New York; and Dr. E. D. Hudson, Jr., of New York.

After the transaction of routine business, the first paper, entitled

CIRRHOSIS OF THE LIVER IN CHILDREN,

was read by Dr. R. Palmer Howard, of Montreal.

He reported two cases in which cirrhosis of the liver was present in children, brother and sister. He exhibited sections of the organ.

DISCUSSION.

Dr. William W. Welch: I recall a case of cirrhosis in a child twelve years of age. He came from the coast of Africa, and suffered with malaria. Both the liver and spleen were deeply pigmented. The clinical features of the case could not be obtained. Most of the cases of cirrhosis of malarial origin have been reported from the coast of Africa. Very little has been brought forward in this country with regard to the malarial origin of cirrhosis.

Dr. F. Forsheimer, of Cincinnati: I have seen two cases that may possibly be called cirrhosis. One was that of a child of eight years. At the post-mortem the characteristic hob-nail liver was found. In this case I considered the cirrhosis due to syphilis. The second case is now under observation in the Children's Hospital of Cincinnati, the patient being in the last stage of cirrhosis. In this case there is a history of syphilis, and the child has hereditary syphilis of the nervous system. To my mind it is clear that syphilis is the most common cause of cirrhosis of the liver in children.

Dr. William Pepper, of Philadelphia: I have the complete records of a case in which cirrhosis of the liver followed measles in a child eight years of age. There was no syphilitic history. During the attack of measles there were symptoms of hepatic disorder, as shown by occasional attacks of catarrhal jaundice. Subsequently the symptoms of developing cirrhosis made their appearance, and death in a comatose condition finally occurred. The whole duration of the case could not have been less than a year. At the autopsy a typical hob-nail liver was found. The liver had been much enlarged, but it had gradually contracted so that at the time of death it was of about the normal size.

OBSTRUCTIVE SAFETY-VALVE ACTION IN THE HEART, AND DIRECT FUNCTIONAL MURMURS,

was the title of a paper by Dr. John Guiteras, of Charleston. In a previous paper, on malignant endocarditis, the author had dwelt upon the significance of mitral direct presystolic murmurs, which were proved by the autopsy to be unconnected with any lesion of the mitral orifice. The lesions were those of intense aortic regurgitation. He had attributed the murmurs to the recoil of the blood upon the mitral leaflets, holding them tense against the stream of blood coming from the auricle. In the opinion of the late Dr. Flint, direct functional mitral murmurs were limited to a small number of cases of aortic regurgitation, but the author thought that functional mitral murmurs were not so rare. Obstructive functional murmurs are common in aortic regurgitation.

Pulmonary systolic murmurs are more frequent than any other form of cardiac murmurs. In examining one hundred consecutive cases, he had found in sixty-two systolic pulmonary-artery murmurs. In these the murmurs were present during tranquil breathing, or during respiration in such a way as to produce changes in the pulmonary circulation. If account is taken of the bruits heard in this region, the proportion becomes greater. Systolic pulmonary murmurs can be developed in the majority of healthy individuals, if we exclude those with thick chest-walls and those who are not intelligent enough to modify their breathing as directed. The author held that such a murmur was a dynamic obstructive valvular murmur, and is produced by the effect of changes of blood-pressure upon the semilunar valves. A certain degree of pressure in the artery must tend to prevent the opening of the valve. This causes a slanting position of the valve, and a narrowing of the orifice, with the production of a sonorous whirl. The fact that such murmurs are not more frequently developed at the aortic orifice is due to the greater power of the ventricle and the wider distribution of the systemic circulation. There are, however, cases in which increased arterial tension is expressed, not only by accentuation of the aortic second-

sound, but by an aortic systolic murmur. Pulmonary-artery murmurs, as heard in ordinary breathing, are confined to the expiratory act, and are loudest at the beginning of the act. The murmur is sometimes only heard with the first beat that occurs with expiration. In order to further develop this murmur, it is only necessary to arrest respiration. It is better to stop breathing during expiration, especially at the end of normal expiration. A full expiration makes the murmur louder. The speaker asked, Are we not justified in assuming that there is a safety-valve action in this attitude of the pulmonary valve, which, together with the leakage at the tricuspid orifice, tends to prevent engorgement of the lungs by retardation of the flow of blood in the systemic veins, so that, continued for a time, it does no harm? On reference to the murmurs of anæmia, the author thought that they were due to some disturbance of the valvular apparatus. In this condition there is a marked reduction in the quantity of blood. The valves require a certain amount of expansion of the vessels in order to allow them to apply themselves to the walls. Venous hums and basic murmurs he thought to be of valvular origin.

Dr. A. L. Loomis, of New York: Many different explanations of murmur within the heart-cavities have been given. We should recognize that they are due to many different causes.

The obstructive mitral murmurs referred to are, I think, of frequent occurrence in connection with aortic disease where there is dilatation and feebleness of heart-power, but on autopsy I have always found such changes in the mitral valves as seemed to me to account satisfactorily for the murmur heard.

I have heard the murmurs readily produced during respiration, but where these murmurs have been persistent I have always found conditions of anæmia and failure of the right heart. It seems to me that the explanation is either hæmic or failure of heart-power. I think that we shall, as we study the cases more, find that they are due, not so much to change in the valvular orifices, as to changes in the heart-cavity and in the heart-walls. Murmurs have come to be of very little pathological significance to me, unless there are other changes associated with them. The worst cases of heart disease that I have met with have had the simplest and least distinct heart-murmurs.

Dr. E. T. Bruen, of Philadelphia: In a case of anæmia which I have recently studied, the blood-corpuscles were reduced from the normal to 1,800,000, with a great reduction in the hæmoglobin. There was also great relaxation of the vascular system; so much so that, as the arm hung out of bed, there was a venous pulse at the back of the wrist. This was attributed by Dr. Osler and myself to relaxation of the capillary vessels to such an extent as to permit the systolic impulse of the left ventricle to force the blood through the capillaries into the veins. There was no venous pulse in the neck. In this case there were murmurs at each of the valves of the heart. As the anæmia improved and the crasis of the blood was restored the venous pulse disappeared and the murmurs gradually lessened, and the man has now no murmur whatever.

Dr. F. C. Shattuck, of Boston: A murmur, by itself, is next to nothing; there must be something besides the murmur to make it of much importance. The author has stated that in anæmia there is a reduction in the quantity of the blood. I would ask, Is not the reduction more in the quality—a corpuscular reduction, and a reduction in the capacity of the corpuscles for carrying hæmoglobin?

Dr. Samuel C. Chew, of Baltimore: With reference to the diagnosis between aortic regurgitant and mitral direct murmurs, I think that the diagnosis can usually be made by attention to the following points: An aortic diastolic murmur, although it may be intense at the apex, becomes manifestly louder as we reach the right side of the sternum, in the second intercostal space. It will then occupy the whole diastole. If the murmur is mitral in origin, it generally will be presystolic, and will be also heard in the scapular region. The aortic murmur is not apt to be heard in the latter situation.

Dr. Beverley Robinson, of New York: I have occasionally found in acute strain of the heart, not necessarily brought about by great muscular exertion, murmurs which unquestionably had nothing to do with organic changes in the heart, and cannot be explained as due to any special modification in the blood. The murmurs seemed to be due to more or less acute dilatation or obstruction of the mitral orifice.

Dr. Israel T. Dana, of Portland: I have had under my observation two sisters, one forty years of age and the other thirty-three. The mother died of organic heart disease. Both of these sisters have had a mitral regurgitant murmur. In the older sister the murmur, after remaining for five or six years, disappeared. It remained absent for one or two years and then returned, and has continued for the past two or three years. In the second case the murmur, after having been present for five or six years, disappeared, and has since remained absent.

A paper by Dr. Hosmer A. Johnson, of Chicago, on

PNEUMATIC DIFFERENTIATION,

was read by the Secretary, in the absence of the author.

The last paper of the morning session was entitled

METHODS OF LITERARY RESEARCH,

by Dr. John S. Billings, U.S.A. The author referred to the best way of using libraries, with especial reference to medical literary work. He also spoke of the great importance of carefully prepared catalogues of books.

Adjourned.

Afternoon Session.

Dr. H. C. Wood, of Philadelphia, read a paper entitled

THE ANTIPYRETIC TREATMENT OF FEVER.

The author had prepared certain propositions, which he read, and then gave what he thought to be the proof of their correctness. The first proposition was: "Fever is a disturbance of calorification in which, through the influence of the nervous system, heat-dissipation and heat-production are both affected. If there be a fever which is produced by the direct action of a poison independently of the nervous system, we have at present no proof of its existence." If an animal's temperature rise, there must be a certain number of heat-units used in producing that rise. If the temperature fall, there must be a corresponding lessened production of heat. In his experiments the agent used to produce the fever has been the pyrogenic principle found in ordinary commercial pepsin. After the substance has been introduced the animal is put into a calorimeter. The animals used in the experiments have been dogs. In the normal animal, heat-production and heat-dissipation are correlated functions. When the poison is injected it is found that heat-dissipation increases at the time that heat-production is diminishing, so that the fall of temperature was in part the result of heat-dissipation and in part the result of diminished heat-production. It is impossible that there should be this wide disturbance of these two functions simultaneously unless the poison which produces the fever acted upon some one central organ, and that must be the nervous system.

Second, "Heat-production is regulated by a nervous apparatus, our knowledge of which is still imperfect." There is certainly an inhibitory centre which depresses or controls the production of heat. It probably does this by acting upon the trophic cells of the gray matter of the spinal cord. It is possible, also, that there is a

centre which, when excited, increases tissue-change, but its existence has not yet been proved.

Third, "Heat-dissipation is regulated through the vaso-motor system, so that vaso-motor paralysis is followed by an enormous loss of animal heat, and, under unfavorable circumstances, by death from cold." If section of the cord is made in such a way as to get vaso-motor paralysis without destruction of the respiratory centres, the heat-dissipation rises enormously. If the animal is kept in a temperature of 50° or 60°, it dies in a few hours of progressive loss of heat. If kept in a warm chamber it lives for days. The cause of the rapid heat-dissipation is the opening of the blood-vessels of the surface of the body.

When these remarks are applied to a study of antipyretics, it is seen that drugs may lower bodily temperature in health or in fever by increasing heat-dissipation. In this way act all agencies which cause vaso-motor paralysis. Antipyretics acting in this way may be called false antipyretics. Then it is conceivable that there may be drugs which act on heat-production through the inhibitory nerve-apparatus, of which mention has been made. Such drugs may for convenience be called true antipyretics. Aconite, veratrum viride, and drugs of that class belong to the false antipyretics. Whether or not there are any true antipyretics has, until recently, been a question which we have been unable to answer. With regard to antipyrin, certain experiments made in the University of Pennsylvania seem to give some positive results. Care must be exercised in these experiments not to confound a normal defervescence with the action of the drug administered. In the dog the use of antipyrin diminishes both heat-production and heat-dissipation, the former being diminished more than the latter. It is probable that heat-production is primarily affected. The question arises whether this result is due to an effect on the circulation. He had found that antipyrin had no effect upon the circulation. The blood-pressure was uninfluenced by its administration. He therefore concluded that the action of antipyrin upon the bodily heat was entirely independent of any action upon the circulation, and the probabilities are, of course, that it acts through the nervous system. Beyond this our present knowledge does not extend.

THE TREATMENT OF TYPHOID FEVER BY ANTIPYRIN AND THALLIN

was the title of a paper by Dr. Francis Minot, of Boston

The following conclusions were reached: 1. Both antipyrin and thallin have a remarkable power of reducing the temperature in typhoid fever. 2. In no case was the use of these refrigerants apparently followed by any unfavorable effect upon the course of the disease. 3. The general condition of the patient was more comfortable after taking antipyrin and thallin, which were often followed by sleep. 4. The refrigerant medication by antipyrin and thallin appears to have no specific or decided effect upon the course or issue of typhoid fever. It often contributes much to the patient's comfort; perhaps indirectly promotes his safety. 5. The effect of antipyrin and thallin in promptly lowering the temperature shows that the danger in typhoid fever does not consist in high temperature alone, and that the latter is rather an index of the violence of the abnormal condition which we call fever, though perhaps adding somewhat to the danger. 6. By the internal use of antipyrin and thallin all the effects which are claimed for the treatment of typhoid fever by the cold bath are readily obtained without the trouble and inconvenience of the latter method, and without exposing the patient to the dangers of exhaustion and shock consequent on the fatigue of removal from bed. 7. These remedies may be given without danger to the youngest patients in suitable doses, and, indeed, their beneficial effects are more decided and the unfavorable consequences are less observable than with adults.

Dr. I. E. Atkinson, of Baltimore: As regards the relative merits of thallin, antipyrin, and antifebrin, I think that the tendency to chilling after the use of thallin is decidedly greater than after the use of antipyrin, while the latter is more apt to produce nausea and vomiting. I am disposed to disagree with the statement that the use of these drugs can take the place of the external application of cold water. It has recently been reported that one observer abroad has treated two hundred cases in private practice by the use of baths with a mortality of nothing; in army hospitals he has had a mortality of five per cent., and in ordinary hospital practice a mortality of less than eight per cent. Although with antipyretics we can reduce the temperature at pleasure, yet the duration of the case is not lessened, and in some cases it has been thought to have been prolonged.

Dr. George L. Peabody, of New York: I have found that certain cases which do not bear the cold bath will bear the use of antipyretic drugs, while, on the other hand, the bath may be used in a certain number of cases in which antipyretics cannot be applied. From clinical experience I have been convinced that the cold bath accomplishes more than the simple reduction of temperature. Its soothing effect upon the nervous system is greater than that accomplished by the reduction of temperature by antipyretic drugs. I believe that in many instances the course of the disease is favorably modified by the use of the cold bath. Another important matter is, that since the introduction of these methods of antipyresis the number of relapses seem to be greater and more fatal. I understood Dr. Wood to say that antipyrin acted solely by diminishing heat-production, and that it did not increase heat-dissipation. I must differ from him on that point. It seems to me that the increase of heat-radiation from the surface is very great, not only where it produces sweating, but also where it does not.

Dr. W. W. Welch, of Baltimore: There is comparatively little evidence that the grave symptoms of fever are referable to the elevation of temperature. There is no doubt that temperatures of 110° to 113° produce serious symptoms, but whether or not ordinary temperatures of 105° to 107° exert any serious action on the body, is a question which is certainly unsettled. It has been shown that rabbits can be kept in a box, with a continuous rectal temperature of 107°, for at least two weeks, provided the precaution is taken to keep the box well ventilated and the animals supplied with moist food. Patients may have a perfectly clear brain and no grave symptoms with a temperature of 106° or 107°. On the other hand, there are severe and fatal cases of typhoid fever in which the temperature has never registered a great height. While in most cases there is a certain proportion between the height of the temperature and the severity of the disease, yet there are certain cases where this proportion does not exist.

Dr. William Pepper, of Philadelphia: I have been disposed to think that antipyrin and antifebrin were superior to thallin. I have not seen any of the dangerous symptoms which have been mentioned by some writers. The action of these drugs seems to be purely through the nervous system. I have seen no effect upon the circulation, upon the respiration, or upon the secretions, save that of the skin. Some of my observations have been of interest with reference to the relative value of the external use of cold water and the internal use of antipyretics. In the sudden acute pneumonias of children, with a temperature of 106° or 107°, with initial convulsions, where the prompt and repeated use of cold baths has been without gratifying results, full doses of either of these antipyretics have produced a remarkably successful effect. In a recent case, in a child with double croupous pneumonia, involving two-thirds of the left lung and one-third of the right lung, with a temperature in the rectum of 107°, and with repeated convulsions, cold baths failed to relieve the symptoms, although repeated at intervals of three hours. Antipyrin in repeated

doses controlled the pyrexia at the beginning and on several occasions during the course of the disease, and after a severe struggle the child recovered. As to the ability of these agents to replace cold baths under all circumstances, the evidence is not adequate. In the sudden hyperpyrexia occurring in the course of rheumatism, I am not prepared to accept the view that these drugs are capable of replacing the cold bath. In these cases we have direct evidence that the high temperature is the cause of the symptoms—at least of the severe nervous symptoms.

Dr. George B. Shattuck, of Boston: It seems to me that antifebrin offers all the advantages of antipyrin, without its disadvantages. It has none of the disadvantages which belong to thallin. Three or four grains of antifebrin accomplishes the same results as are produced by a larger dose of the other drugs. The disagreeable symptoms which some writers have referred to as following antipyrin are probably due to the fact that they follow the original recommendation, and give two grammes of the drug. The same benefit can often be obtained from one gramme and often from seven grains. With reference to the point suggested by Dr. Welch, I would say that, whether pyrexia is or is not a dangerous feature of the disease, we find, clinically, that where a patient has high fever, is irritable, impatient, and uncomfortable, the administration of one of these antipyretics or the external use of cold water produces a tranquil and refreshing sleep, and the patient awakes in a condition much better to continue the struggle with the disease.

Dr. J. C. Wilson, of Philadelphia: A recent observation which I have made is interesting as bearing on the question of heat-dissipation. I have lately been treating a case of typhoid fever in which from time to time antifebrin in five-grain doses was given. These were repeated whenever the temperature reached 104°. This caused copious sweating, with the usual reduction of temperature, amounting to three and one-half or four degrees. On the last occasion one ninety-sixth of a grain of sulphate of atropia was given with the antifebrin. No sweating occurred, and the temperature was reduced one and one-half degrees.

Dr. James T. Whittaker, of Cincinnati: I would differ from the gentlemen who seem to accept the view that fever is a neurosis. We have, I think, no proof that the nerve-centres are distinctly irritated, and we have no proof that the agents which reduce fever act directly on the nervous centres. Is it not more probable that the antipyretic action is really an antimicrotic action? We have some observations which go to show that the disease is caused by bacteria, or, if not directly by bacteria, by some of their products—the ptomaines. Would it not be more rational to study the habits of these bacteria and address ourselves rather to the removal of the cause than to the counteracting of the effects?

Dr. H. M. Lyman, of Chicago: I am disposed to regard their great value as proceeding not so much from their power to reduce temperature as from their general effect, especially upon the nervous system. I regard them as valuable adjuvants in the treatment of disease, largely from their hypnotic and tranquillizing effect upon the nervous system, to which allusion has already been made. I have observed that in many instances where, in abrupt febrile affections, relief has not been secured from antifebrin and antipyrin this failure is frequently due to the presence of the condition we call rheumatic, and there salicylic acid gives the relief that we fail to get with the antipyretics.

Dr. John Guiteras, of Charleston: I have had some experience with these drugs in the treatment of the continued fevers of warm climates, but here the results have been rather negative, and have shown the advantage of stopping their use after they have been continued for a certain length of time. I have been called in consultation where the drug had been continued for ten or fifteen days, each time that it was given producing a certain reduction of the temperature, but having no permanent benefit, and the patients have begun to improve as soon as the drug was stopped. The effect of cold-water baths in these continued fevers of the South has seemed to me to be more beneficial. If continued for two or three days they often favorably modify the course of the disease.

Dr. George L. Peabody, of New York: There is no question in my mind that a considerable proportion of cases of typhoid fever can be aborted by antiseptic treatment of the intestinal ulcers with naphthalin or resorcin. For the past two years I have treated all cases coming under observation during the first ten days of the disease with a calomel purge (ten gra.) followed by naphthalin in such doses that at least seventy or eighty grains are taken during the twenty-four hours. Under this treatment I have without doubt succeeded in aborting many cases in which the symptoms were quite pronounced. I have not succeeded in cases coming under observation at the end of the second week.

Dr. H. C. Wood, of Philadelphia: In regard to the dissipation of heat by sweating, I would state that in the dog, on which the experiments were made, there are but few sweat-glands. Sweating in man does undoubtedly cause a dissipation of heat.

Dr. James Tyson, of Philadelphia: In a recent case of rheumatism the temperature suddenly went up to 105°, with alarming brain-symptoms. Antifebrin, in five-grain doses, failed to produce any effect. The patient was then put into a cold bath, and the temperature of the water gradually reduced to 72°. The discomfort experienced by the patient then prompted his removal from the bath. The thermometer in the rectum showed a reduction of only one-half of a degree, but within the course of half an hour the temperature fell three degrees. I scarcely think that this was a natural defervescence, but must attribute it to the effect of the bath. The fall in temperature was followed by a disappearance of all the symptoms, and the recovery of the patient.

Dr. R. Palmer Howard, of Montreal: I want to emphasize the fact that internal antipyretics and the cold bath are not equivalents—they are substitutes—and important auxiliaries to the physician. These measures relieve special symptoms, but whether or not they shorten the duration of the disease is a question not yet settled. Another important point is with reference to relapse in typhoid fever. This is a subject which requires investigation. I think that every relapse, so called, is due to the absorption of fresh poison. It is really a fresh attack. It is really an initial attack. It runs a severe course, and often proves fatal.

Dr. Henry Hun, of Albany, reported in detail the histories of twenty-nine

CASES OF SEWER-GAS POISONING

coming under his observation, in which various diseases appeared to have been due to the inhalation of sewer-gas. He thought it probable that the following diseases may result from sewer-gas poisoning: Vomiting and purging, separately or combined; general debility, fever, sore-throat of a diphtheritic type, neuralgia, and perhaps, also, myelitis of the anterior horns. These conditions are frequently combined. Fever is frequently associated with the other symptoms. There is one group of symptoms which is almost always present—that is, loss of appetite, extreme prostration, and pain in the head. When this occurs as a chronic condition we are justified in suspecting that the patient is suffering from sewer-gas poisoning.

Dr. Israel T. Dana, of Portland, Me., reported the following

CASE OF ANEURISM ON THE ABDOMINAL AORTA.

A. H——, a man aged thirty, of previous robust health, was found, August 6, 1886, emaciated, feeble, anæmic,

dyspeptic, and with very frequent, unsteady, and irregular pulse. The most prominent symptom was a constant sensation of throbbing and pulsation centring in the epigastrium. Exacerbations occurred on slight exertion or excitement.

In August, 1884, he fell ten feet, striking on small of back. Gradual failure of strength and endurance appeared. He would get tired soon, and more easily out of breath. There was gradual deterioration of health until, in latter part of June, 1886, he was utterly incapacitated from all labor. Exploration of abdomen anteriorly revealed existence of a small squabby incapsuled tumor just above the level of the umbilicus. Single impulse related to cardiac systole; no back-stroke; distinct blowing sound. On examination posteriorly there was found a distinct independent centre of motion and sound. The sound was double, sharper and more intense than that heard in præcordial region, and possessed a well-marked "booming" quality. Between this centre of sound and the lower left interscapular region, where the normal heart-sounds could be faintly heard, there intervened an area of silence.

The diagnosis was small traumatic aneurism of abdominal aorta, just after its passage through diaphragm; also some inflammation of aortic coats higher up.

The treatment consisted of (1) absolute rest in bed for two months; (2) restricted diet of bread, meat, milk, and cocoa, with amount limited; (3) iodide of potassium, twenty grains four times a day.

Immediate improvement ensued within first week, and continued gain in power, till by the middle of November he could walk and ride about carefully.

On May 9, 1887, he began light work at the paper-mills again.

He had regained the twenty-five pounds of lost weight, ate well, slept well, and had but little palpitation, though excitement, physical or emotional, readily induced slight return of some of the old sensations.

Physical examination at this date revealed anteriorly the existence of the aneurismal mass, perhaps a little diminished in size, while the blowing sound was scarcely audible. The impulse and expansion were markedly reduced. On examination posteriorly the independent centre of pulsation and double sound was found, but both motion and sound were greatly reduced in amount and the booming quality was gone.

It was concluded that a practical cure had taken place, the sac having become largely filled up with concentric layers of fibrin, and that reduction of the existing inflammation of aortic coats higher up had been effected.

The chances of final complete recovery were not considered encouraging. The circumstances of the patient were not favorable to such rest and tranquillity of mind as might be desirable, and even with all external conditions at the best, there would yet be too many dangerous liabilities remaining, such as embolism, pyæmia, atheromatous degeneration, etc. The quick improvement under treatment was noticeable. The patient himself attached great value to the iodide of potassium, which he still takes, feeling so much better while taking it that he is unwilling to leave it off.

Evening Session.

A discussion on

HEMORRHAGIC INFARCTION

was opened by Dr. W. W. Welch, of Baltimore, referee.

The author presented as the result of his studies the following conclusions: 1. The blood which produces hemorrhagic infarctions comes chiefly, if not exclusively, from the collateral vessels. 2. Hemorrhagic infarctions in the intestine cannot take place merely from a reflux of blood from the veins. 3. The blood-pressure is very low in the region where hemorrhagic infarction occurs, in consequence of occlusion of the main artery. 4. A certain degree of force of the collateral circulation is required to produce a hemorrhagic infarction. 5. No positive proof exists that a change in the vascular walls is essential to the production of a hemorrhagic infarction. 6. The hemorrhage occurs by diapedesis. 7. Where hemorrhagic infarction has taken place, the large and small veins are widely dilated with blood and the arteries contain a smaller quantity of blood than normal; there is stasis in many of the veins and capillaries.

Dr. William Osler, of Philadelphia, the conferee, referred to the clinical aspects of the subject, and reported the following case: J. M——, aged twenty, admitted to the Philadelphia Hospital on October 10, 1886. He had never had syphilis, and was a healthy-looking man. He presented a clear history of typhoid fever, with a sickness of six weeks two years previously. His present illness began with diarrhœa one week before admission. For two days he had attacks of bleeding at the nose. There was a temperature of 102°, with pain in the abdomen. There was no cardiac murmur, and examination of the lungs gave negative results. The splenic dulness was increased. By October 15th the temperature had reached 103°. There was almost constant delirium. There was some diarrhœa. Coldness of the feet appeared, and continued to increase in degree and extended up the leg. The legs became livid, and no pulsation could be detected in the femoral and popliteal vessels. The patient died on the 17th. It was supposed that there was thrombosis of the iliac veins, with gangrene of the legs, which is one of the rare sequences of typhoid fever. At the autopsy it was found that the lower portion of the abdominal aorta, and also the two iliac arteries, were plugged with thrombi. There was general peritonitis; the right kidney presented a red-brown infarction. There were no ulcerations in the bowels, no endocarditis. The lungs were normal. There was an infarction in the spleen. During life the blood was examined for microbes, but none were found. After death microbes were found in the spleen.

Hemorrhagic infarctions of the liver, under ordinary circumstances, are impossible. A. B——, a hard drinker, was admitted to the hospital on September 27th. His illness began in the previous June, with vomiting and swelling of the abdomen. The dropsy steadily increased. He died two days after admission. At the autopsy a large amount of fluid was found in the peritoneal cavity. There was nothing special found in the heart or lungs. The liver was remarkably cirrhotic. Through the right half of the right lobe there were scattered numerous reddish-brown areas. The walls of the portal vein were thickened, and a large brown thrombus occupied the upper portion of its trunk. The branches passing to the right lobe were filled with clots. The hepatic artery and vein were normal. In this case the hemorrhagic infarctions were in all probability due to the cirrhosis of the liver, which had caused more or less obstruction of the branches of the hepatic artery. The only other case of infarction of the liver which the speaker had been able to find was one reported by Recklinghausen.

In the intestine hemorrhagic infarctions are met with in two forms, one involving the mucosa, the other affecting the entire gut. The former not infrequently ends in ulcerative necrosis. The latter form of hemorrhagic infarction is not common in man. In the horse it is frequently seen resulting from thrombi formed from verminous aneurisms of the mesenteric and its branches. This is a common cause of the severe and fatal colic so frequently seen in these animals. In conclusion, the speaker referred to the fact that in the lung it was not uncommon to have a vessel blocked without the production of an infarction. An occasional cause of thrombotic infarction is local disease of the pulmonary artery. It sometimes results from the endarteritis induced by beginning tubercular processes.

Adjourned.

(To be continued.)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, May 6, 1887.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. CLEMENT CLEVELAND exhibited a

SELF-RETAINING SPECULUM,

and demonstrated its use upon a patient. It consisted of two blades like that of the ordinary Sims speculum, each having a flange, and connected by a bar one inch and a half long. The space made by this connecting-bar was sufficient to include the tissues between the posterior wall of the vagina and the integument between the nates. To be used with the speculum was a belt which went around the body, and from it a strap passed through a slot at the end of the blade, back under a bar soldered to the connecting-bar, and then it returned upon itself and was hooked, so as to produce the required degree of tension to hold the instrument in position without the aid of an assistant.

DR. SAMUEL SEXTON then read a paper [see p. 649] entitled

BOXING THE EAR.

DR. JAMES B. HUNTER then reported cases in which he had used

AVELOZ IN THE TREATMENT OF CANCER.

The milk of aveloz, a specimen of which was shown, is the product of a plant growing in Brazil, one of the euphorbiaceæ, many varieties of which are well known for their irritant and acrid juices. He had not been able, from any botanical works at his disposal, to ascertain exactly the position of the plant furnishing the juice known as the milk of aveloz, but it appeared to be closely allied to the *Hura crepitans*, the milk of which is described by the older botanists as possessing extraordinary properties as an irritant. Boussingault made an examination of some of the juice, and was attacked, he says, with a severe form of erysipelas. The courier who brought the juice, as well as the inhabitants of the house in which he spent the night on his way, were also attacked with severe inflammation of the skin. Another species of the same family growing in Brazil is the *Hippomane mancinella*, or manchineel tree, about which there are fabulous accounts, as that it is fatal to life to sleep beneath its shade. It is true, however, that a drop of the juice of that tree applied to the skin will quickly raise a blister full of serum. It is not surprising, therefore, that the milk of one of the euphorbia family should be possessed of very active properties.

Several years ago a small quantity of the milk of aveloz was sent from Brazil to the authorities at Washington, and distributed for trial. Then for a time none could be obtained. Later it was to be purchased of a gentleman in this city, John T. Kirby, 16 Beaver Street. The depôt for its sale is in Pernambuco, the juice being collected chiefly in the province of that name. The preparation is said to be patented by the Government of Brazil, and its use is endorsed by the Central Board of Health of Rio de Janeiro.

IT HAS A LOCAL REPUTATION FOR THE CURE OF ULCERS OF ALL KINDS,

especially syphilitic ulcers, and for the cure or relief of cancer. It is claimed by Numa Pompilio, who signs himself Surgeon-Dentist, and who seems to act as agent for Gitirana Costa, who prepares the drug, that it is used extensively in the Pedro II. Hospital in Rio, and with excellent results.

Two preparations are furnished, one of which is recommended for open ulcers, and the other for cases of cancer in its early stages. The principal or only appreciable difference appears to be in the degree of inspissation.

The method of using the drug advised is, that the affected surface be thoroughly cleaned with a carbolic lotion, and dried. The juice is then applied freely with a soft brush, retained in place by lint or cotton, and covered with light rubber or gutta-percha tissue. The purpose of the application is to produce the effect of a caustic. Special care is necessary to prevent contact with sound tissues, as it is extremely irritating. The application is repeated every three or six days, according to the condition. His own experience had been confined to cases of epithelioma of the cervix. He first alluded briefly to the experience of others. Its application to disease of the breast is said to be very painful. There is not usually much pain in its use on the cervix uteri.

Dr. Velloso, in the *British Medical Journal*, January 6, 1887, claimed to have cured several cases of epithelioma of the face and lips, in which site the drug was said to cause severe pain.

Dr. W. H. Bolling, of Louisville, who received some of the first specimens of the remedy sent to Washington, reported marked improvement in several cases of epithelioma of the face; and one case of probable or apparent cure. It was used in Dr. Bolling's cases as an escharotic, for the destruction of diseased tissue.

Dr. Janvrin, of this city, had used the drug in many cases with marked benefit.

During the past three years Dr. Hunter had applied the milk of aveloz in many cases of

EPITHELIOMA OF THE CERVIX,

and though its effect had often been negative, in a certain number it had produced results that he had not obtained by any other means. In cases of spongy, easily disintegrated cervices, it had left a better surface than nitric or chromic acids, or than the actual cautery. It had also seemed to him that the recurrence was delayed longer than after the ordinary caustics. He had confined its use to cases where the knife was not applicable, or where operation was not allowed. In some cases he had been surprised at the comparatively healthy condition of the surface remaining after the eschar came away, and surprised also at the long interval that elapsed before there was fresh breaking down.

One of the effects of a free application of the juice to a diseased surface is to promote a copious serous discharge, thus depleting the congested vessels. In some cases a marked difference has been effected in the character of the discharge, which has become and remained for a long time almost inoffensive.

The following cases were selected as illustrative of the treatment and exemplifying its results, of which all that could be said was, that they were in some respects better, as to the arrest of the disease, and as to the comfort of the patients during its progress, than those afforded by many of the usual methods. As far as he could judge at present, he should not use the aveloz with any expectation of effecting a cure; but it seems probable that it may do more than some other remedies toward arresting the progress of the disease, and perhaps prolonging the period during which surgical treatment may be employed with some hope or promise of success.

He had not lost sight of the fact that some cases of cancer of the uterus undergo changes in their progress that might erroneously be attributed to the remedies used; but after making due allowance for that source of error, there still remains something to be said in favor of the drug in question.

CASE I.—Mrs. A——, aged thirty-nine, mother of four children, had been in good health until one year before seen, when there was a profuse watery discharge, very offensive, with occasional hemorrhages. The aveloz was applied at first every third day, and later once a week. There was marked improvement for seven months; the disease seemed almost to stand still.

THE APPLICATIONS WERE FOLLOWED BY SOME PAIN,

but the discharge very much diminished, and became less offensive. The patient died about one year after she was first seen.

CASE II.—Mrs. B——, aged forty-one, mother of two children, had amputation of the cervix, with recurrence six months later. There was a profuse offensive discharge, and the surface bled on the slightest touch. The aveloz was used so freely as to destroy the tissue deeply. The result was such as to rouse a suspicion as to an error in diagnosis. The improvement was of nearly a year's duration. In this case nitric and chromic acids had been used without benefit.

CASE III.—Mrs. C——, aged fifty, mother of four children. The use of aveloz seemed to arrest the breaking down of the cervical tissue. For eighteen months there was no material change. Then there was a sudden redevelopment. No opportunity was afforded of a further trial of the drug. The long period of freedom from all the urgent symptoms was a remarkable feature in the case.

CASE IV.—Mrs. D——, aged fifty-five, had, when first seen, been suffering from hemorrhages, and a very offensive discharge, for about six months. After using the aveloz there was less hemorrhage, but the offensive discharge continued. There was a change in the appearance of the diseased portion of the cervix, and it could be touched without bleeding as at first. The use of the aveloz was suspended several times, and each time there was an aggravation of the symptoms, and after its use the diseased surface could be examined more thoroughly without breaking down. In this case the patient had suffered the constitutional effects of the disease before coming under treatment, and little was to be expected from any local application.

CASE V.—Mrs. E——, aged fifty, mother of three children, had enjoyed exceptionally good health until one year before the time when first seen, October, 1886. She had been told she had a cancer, and was prepared for the worst. After three applications of the aveloz a slough came away, and for the past six months there has been no apparent change in the condition. The surface remains unbroken, and there is no evidence of extension in any direction. Repeated applications have been made, but the first apparently did the most good, as there has been no discharge and no hemorrhage since they were made. The case is still, and will be watched with interest.

The class of cases in which this drug seems at least worthy of a trial are those where the skin or mucous surface is broken—that is, in the early stage of ulceration, and before there are any constitutional symptoms.

DR. ROBERT F. WEIR then read a paper [see p. 652] on

PERFORATION OF THE APPENDIX VERMIFORMIS, WITH A PLEA FOR EARLY RESORT TO SURGICAL INTERFERENCE.

DR. W. T. BULL thought that the Society was under obligation to Dr. Weir for bringing this most important subject before it. So far as the performance of laparotomy for this variety of perforation was concerned, he thought that the record, at the present time, was not very satisfactory, but at the same time it was encouraging. He noticed that Dr. Weir had thrown Homan's case out, and it was very proper that he should have done so, because it seemed evident that the abscess could have been opened without involving the peritoneal cavity at all. Even though one did not feel certain of his diagnosis, he believed that a limited exploration could be practised with very much less danger than what is ordinarily called a complete laparotomy. Given a doubtful case, one might, even without an anæsthetic other than cocaine, make a small incision which would permit the introduction of one or two fingers, and by the exploration that could be done through such an opening he thought that, on the average subject, not too fat, a correct diagnosis could be made, or at least it could be determined whether or not the disease was connected with parts in the right iliac fossa. Such an operation could be resorted to very much earlier than an ordinary complete laparotomy.

So far as the general management of the case was concerned, Dr. Bull thought that thorough washing out of the abdominal cavity was very desirable, but at the same time he confessed that he felt somewhat skeptical with regard to the reports of laparotomists who claim to cure general purulent peritonitis by any kind of irrigation. He doubted whether general purulent peritonitis had ever been cured by that method. He was unable to see how anyone could

WASH OUT THE ABDOMINAL CAVITY

and remove all the purulent and other inflammatory products. He could not help believing that the reported cases of cure had been cases of localized peritonitis. Such cases can be cured by irrigation, perhaps. He believed that surgeons were fast coming up to the point where they would have a much better chance for reversing the mortality record in these cases, providing that physicians watch with the greatest amount of care the development of the symptoms. He would like to ask Dr. Weir if he was thoroughly satisfied that he would not have been likely to have cured his patient by such an exploration for perityphlitic abscess.

DR. WEIR said that he should probably have struck the abscess, and probably would have given the patient a better chance than was afforded by his operation.

DR. A. H. SMITH asked, why advocate laparotomy in the median line? Why not make the incision in the region of the cæcum?

DR. WEIR replied that there was no difference in the risk, probably, between the two regions, but the chances were that in some cases the incision in the median line would prove to be the one through which the pus could be reached.

DR. SMITH referred to a case in which stercoraceous vomiting was present to a very marked degree, yet there was no intestinal obstruction. The case was one of probable ingestion of corrosive sublimate. The odor of the vomited matter was distinctly fecal and not gangrenous.

DR. A. A. SMITH asked Dr. Weir what he meant by the expression "very early?"

DR. WEIR replied that he could not fix the time absolutely, but that certainly the

EXPLORATORY INCISION SHOULD BE MADE BEFORE THE END OF FORTY-EIGHT HOURS.

DR. SMITH said: Suppose there is no localized peritonitis, will the exploratory incision do harm?

DR. WEIR answered that the exploratory incision was comparatively harmless when inflammation was not present. He was unable to say how much, if any, would be added to the danger by the operation.

DR. SMITH asked if there were not many cases in which recovery took place without an operation. He did not wish to be regarded as unduly critical, but was merely desirous to obtain information which would enable him to do the best for the patient when brought face to face with a serious case, and particularly as to when abdominal section should be advised. He was of the opinion that

IT SHOULD BE DONE VERY EARLY,

and he wished to ascertain particularly how much the gravity of the case would be increased by an operation within the first forty-eight hours.

DR. WEIR said that cases did occur in which recovery took place without any operation. As to the danger added by an early exploratory incision, he could only refer to cases in which it had been performed without any ill effects; for example, Billroth had opened the abdomen in twenty-seven cases, and all the patients recovered.

DR. SMITH: And if there is no inflammation the operation is less harmful?

Dr. Weir: It is a comparatively safe procedure. Whether it adds to the inflammation already in progress he was unable to say.

Dr. A. H. Smith referred to the case of a woman under observation, who had, at about the middle of Poupart's ligament, a tender spot with some pain on moving, and some sense of resistance on palpation. There was no rise of temperature, and no great amount of suffering, and yet there was a slight swelling and resistance there which were not present upon the opposite side. Was the indication present for an operation?

Dr. Weir said it must be remembered that perityphlitis in females was exceptional; it was the rule that it occurred in males. And there were so many other causes of inflammatory troubles in that locality in females that he thought such a case could be watched safely. It was

THE SEVERE CASE PROGRESSING

with marked symptoms which he had under consideration, and when it was ascertained that pus was present it should be let out.

The Society then went into executive session.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Ninth Annual Congress, held in New York, May 26, 27, and 28, 1887.

(Concluded from page 648.)

Friday, May 27th—Second Day—Morning Session.

The Association was called to order by the President.

The first paper was an elaborate one, read by Dr. Frank Donaldson, Jr., of Baltimore, entitled,

FURTHER RESEARCHES UPON THE FUNCTION OF THE RECURRENT LARYNGEAL NERVE,

in which he reviewed warmly a paper read before the Association by Dr. F. H. Hooper, of Boston, at a former meeting, and then reported the results of a series of experiments performed in the biological laboratory of the Johns Hopkins University to prove that Dr. Hooper's criticisms upon his paper were not well founded.

Dr. Franklin H. Hooper, of Boston, then read a valuable paper on

THE ANATOMY AND PHYSIOLOGY OF THE RECURRENT LARYNGEAL NERVE,

in which was detailed a series of experiments performed in the physiological laboratory of the Harvard Medical School.

These papers were discussed by Drs. J. H. Hartman and J. N. Mackenzie, of Baltimore; F. I. Knight and S. W. Langmaid, of Boston; B. F. Westbrook, of Brooklyn, on invitation by M. A. Starr, of New York, and by the writers.

Afternoon Session.

The first paper was read by Dr. W. C. Glasgow, of St. Louis, on certain

MEASURES FOR THE RELIEF OF CONGESTIVE HEADACHES.

The variety of headaches considered in the paper was that from over-distention of the blood-vessels; the so-called brow or catarrhal headache occurring frequently at the menstrual period and called uterine headache, etc. The cavernous bodies are in a state of tension, and the measure for the relief of the pain which he had practised with most satisfactory results during the last four years was local abstraction of blood, by pricking these bodies with a lance-headed probe. The quantity of blood drawn rarely exceeded one ounce, and in some cases a single drachm gave the desired relief. The bleeding might be repeated.

Dr. J. N. Mackenzie, of Baltimore, had had a similar experience, and was pleased to hear that his view concerning the congested condition of the cavernous bodies during menstruation had been noticed by Dr. Glasgow.

Dr. C. C. Rice, of New York, said his experience had differed from Dr. Glasgow's; that he had regarded the cause as hypertrophic changes producing pressure; and that his treatment had been mainly by the use of the galvano-cautery, and he had not found it necessary to draw blood.

Dr. H. Allen, of Philadelphia, regarded these cases as owing to pressure effect due chiefly to deflected septum.

Dr. Sajous, of Philadelphia, while he thought that Dr. Allen's theory would explain a number of cases, believed that headaches originating in the nasal cavity were due to hyperæsthesia of the mucous membrane.

Dr. Bosworth, of New York, questioned very seriously that the point of contact of the mucous membrane in the nasal cavity was a pathological condition.

As to what the special morbid lesion was that produced headache, he thought we were yet very far from knowing exactly.

The discussion was continued by Dr. Allen and by Dr. Glasgow, who said that it was *congestion*, not hypertrophy nor hyperæsthesia, that constituted the basis of his paper, and that the condition of the cavernous bodies was evidence of the congestion above. He spoke only of the condition dependent upon those elastic sanguineous swellings which yielded to gentle pressure with a probe.

LEUCOPLAKIA BUCCALIS,

by Dr. Glasgow, of St. Louis, was read by title.

THE TREATMENT OF LARYNGITIS IN PROFESSIONALS WHO ARE UNABLE TO REST.

Dr. Solis-Cohen, of Philadelphia, opened the discussion on this subject, and said that he had been unable to treat laryngitis better in professionals than in other people. For the relief of acute hoarseness, he had used a brisk emetic, allowing the patient to rest until the performance begins, in the meantime not using the voice, but sucking pieces of ice, and applying cold compresses to the neck.

In cases of chronic laryngitis, he uses weak solution of zinc, gr. ii. to the ℥i., as a spray. In the intervals of the play it was well to allow the person to inhale the compound tincture of benzoin. Other remedies which could be used with benefit are turpentine, terebene, eucalyptol, etc., as inhalations. He was not aware of any special method adapted to this class of cases.

Dr. De Blois, of Boston, had found that these patients did not recover without rest. If able to spare twelve hours, very excellent results would follow the use of nitrate of silver, and disastrous results followed the use of cocaine.

Dr. Beverley Robinson, of New York, believed, so far as acute cases were concerned, that there were milder, and equally efficient, measures than emetics. He uses internally triturate tablets of chloride of ammonium repeated every fifteen or twenty minutes, with local applications of carbolized spray, modified Dobell's solution, two, three, or four times a day.

As to the chronic forms, he had used locally the tincture of iron with glycerine, and had not seen any special benefit from the use of internal remedies. The use of the faradic current twice a day had also been serviceable.

Dr. Bosworth, of New York, did not believe that there was any such thing as laryngitis; the seat of the disease was in the nasal passages. Eliminate the cold in the head with cocaine, and thin the membrane down with chromic acid, and the disease of the larynx would take care of itself. He had not seen any reaction follow the use of cocaine, and he had used it by adding twelve

grains to sufficient zero (fluid) cosmoline to dissolve it, and use as a spray with a hand-atomizer every hour or two hours, and at the same time inhale it by the mouth.

Dr. Robinson said that what Dr. Bosworth had stated concerning cocaine was incorrect, and also that laryngitis does occur independent of nasal troubles.

Dr. Sajous, of Philadelphia, said that, certainly and most emphatically, the action of cocaine in the larynx was pernicious. He has found that sprays in these cases were rather irritating, and contents himself with the internal use of one grain of quinine with one-fourth of a grain of nux vomica, repeated, perhaps, every two hours. The faradic current also was beneficial. Coca wine also was advantageous.

Dr. Glasgow, of St. Louis, had cured laryngitis without touching the nose. In acute cases, those in which the person *must* perform, he makes an application to the *larynx* of carbolized iodine, which relieves the congestion and gives power to the vocal cords.

Dr. Rice, of New York, thought well of the use of cocaine and cosmoline, but believed that it was the cosmoline which did the work. He had had better results with vaseline than he had had with astringents.

Dr. Asch, of New York, had found muriate of ammonia to be one of the most useful of internal remedies. He thought it could be best employed in solution with compound licorice mixture. This, with soothing inhalations and the use of ordinary remedies, barring emetics, will quickly afford relief.

In the chronic cases it is almost impossible to effect a cure, and local remedies must be used. Astringents had served him best, and his favorite was the perchloride of iron, thirty to sixty grains to the ounce of water, and applied with the brush. In most opera singers there was some hepatic disturbance which needed attention.

Dr. Hooper, of Boston, spoke of a class of cases in which the voice was altered simply from over-exertion, and in which electricity externally, and the internal use of aromatic spirits of ammonia, thirty or forty drops in a tumbler of water, gave excellent results.

Dr. Mackenzie, of Baltimore, cautioned against the injudicious use of cocaine in disease of the nose and throat. He never used it just before the person was to go upon the stage. In the larynx its effect was something terrible, second only to hanging.

Dr. Westerbrook, of Brooklyn, spoke of derangements of the digestive apparatus which predisposed to the troublesome conditions under consideration, and favored the use of an emetic, or calomel and jalap, to be followed by the mineral acids in small doses frequently repeated. He did not favor the use of cocaine.

Dr. Langmaid, of Boston, thought it should be easy for anyone to cure this class of patients, with so many remedies recommended as very excellent; but as for himself he had not found them easy to cure.

Dr. C. C. Rice, of New York, then read a paper on

GLANDULAR AND CONNECTIVE-TISSUE HYPERTROPHIES OF THE LATERAL WALLS OF THE PHARYNX,

in which he directed attention especially to the different pathological conditions.

Dr. Charles H. Knight, of New York, read a paper entitled

THE GALVANO-CAUTERY IN THE TREATMENT OF HYPERTROPHIED TONSILS.

He had punctured the tonsils in two or three places at each sitting, and with five or six séances had had very satisfactory results. It was especially applicable to the cases in which a hemorrhagic diathesis was present.

The paper was discussed by Drs. Sajous, of Philadelphia; French, of Brooklyn; MacCoy, of Philadelphia; B. Robinson, of New York; Ingals, of Chicago; Rice, of New York; Allen, of Philadelphia; Delavan, of New York; J. Solis-Cohen, of Philadelphia; and Asch, of New York. The discussion was largely on the occurrence of hemorrhage in tonsillitis, and it followed the usual course, namely, some fearing its occurrence, others regarding its occurrence as rare; some looking upon the operation as an exceedingly simple one. and others as one of a great deal of importance. About the same difference of opinion was expressed concerning the utility of the galvano-cautery.

Dr. Beverley Robinson, of New York, gave a

NOTE ON A FREQUENT CAUSE OF NASAL HEMORRHAGE.

Ulcerations in atrophic rhinitis, according to his experience, were one of the most frequent causes of nasal hemorrhage. He directed attention to the fact that he had been unable to detach the crusts from these ulcers either by douches or sprays so well as by the use of ointments, which in the course of two or three days enabled him to blow them out. The best ointment for that purpose was the ammoniated mercurial of the Pharmacopœia, made up with vaseline, one-half the full strength. After plugging the nostrils, especially in children, he has found flexible probes most useful. He had never found anything which arrested the hemorrhage so well as sheet sponge. He had used it by cutting it into long strips and pushing it into the nose until the bleeding stops.

The communication was discussed by Dr. Sajous, of Philadelphia.

Saturday, May 28th—Third Day—Morning Session.

The Association was called to order by the President, and Dr. S. W. Langmaid, of Boston, read an exceedingly valuable paper on

CONSTITUTIONAL CAUSES OF THROAT AFFECTIONS.

However important and interesting the morbid changes in the upper air-passages may be locally, the important lesson should be learned that they have underlying constitutional causes which must be removed in order to effect a cure. Syphilis, alcoholism, rheumatism, and gout, etc., were ever at work, and their influence must be combated. Local treatment was in the nature of repair, while constitutional and hygienic treatment must be in the direction of the renewal of normal processes.

Dr. Glasgow, of St. Louis, regarded the paper as one of the most timely which had been presented to the Association. He regarded the statement made by Dr. Daly, of Pittsburg, that the laryngeal physician should become a laryngeal surgeon, as one tending to do much harm, and it had done much to retard progress in this department of medicine.

Dr. J. Solis-Cohen, of Philadelphia, seconded the commendations of Dr. Glasgow, and said that if he could have his way, the Committee on Publication would be instructed *to print it in capitals.*

Dr. Asch and Dr. Delavan, of New York, added their hearty and forcible commendations of Dr. Langmaid's paper.

PAPERS READ BY TITLE.

"Affections of the Crico-arytenoid Articulation," by George W. Major, M.D., of Montreal;

"Cancer of the Larynx," by Hosmer A. Johnson, M.D., of Chicago; and

"A Case of Recurring Laryngitis Hemorrhagica," by C. E. Bean, M.D., of St. Paul.

Dr. Morris J. Asch, of New York, then read a paper in which he reported a case of

STENOSIS OF THE LARYNX

treated by divulsion and systematic dilatation. The opening of the larynx was diminished to one-third its normal size. The dilatation was accomplished by Schroeder's hard-rubber tubes. It was a case of hypertrophic laryngitis below the vocal cords, and the relief afforded by treatment had been permanent. He preferred this to any other method in this class of cases.

Dr. Cohen, of Philadelphia, had not had the courage to attempt to dilate without preliminary tracheotomy. He believed that it was better to perform tracheotomy first, and then pursue the most active measures possible for the relief of the stenosis.

Dr. Knight, of Boston, said that Schroeder's method had been very slowly popularized in this country. He regarded it as a sub-glottic laryngitis of some kind, as had been expressed by Mackenzie, of London, and would discard the name *corditis*, etc.

Dr. Morgan, of Washington, related a case in which he used dilators without permanent benefit, and in which he kept the disease in abeyance by constitutional measures and local applications. He recommended from time to time tracheotomy, to be followed by dilatation, but the patient declined, and finally died suddenly of laryngeal spasm.

Dr. Delavan, of New York, believed that the method of treatment by dilatation would receive important modifications by O'Dwyer's method of intubation.

Dr. Asch spoke of some theoretical objections to O'Dwyer's method for the treatment of these cases. He agreed with Dr. Knight that the term *corditis*, etc., should be abandoned. He regarded it as one of the advantages of this method that tracheotomy was avoided.

Dr. D. Bryson Delavan, of New York, then read an elaborate paper on

THE ETIOLOGY OF DEFLECTIONS OF THE NASAL SEPTUM,

in which he had gathered the scattered views on the causes, which were generally admitted to be obscure. After discussing the predisposing causes, as race and diathesis, he spoke of the exciting causes under the headings, traumatism, local malnutrition, and occlusion of the respiratory passages of the nose.

Dr. Morgan, of Washington, had been able to trace his cases to traumatism almost invariably, when the history had been carefully studied. He had seen but few cases in the African, but whether or not this was real exemption he was unable to say.

Dr. Donaldson, of Baltimore, was also of the opinion that perhaps it was less frequent in the African than among the whites.

Dr. Solis-Cohen, of Philadelphia, had noticed that high-arched palate and deflected septum go together in a majority of cases, perhaps; but he had also seen many cases in which there was deflected septum without high-arched palate, and also high-arched palate without deflected septum. A great many children under *seven* years of age have deflected septum. He thought that the question of traumatism was a difficult one to settle. So also it was difficult to get at the exact influence of racial peculiarities. Over and over, he had seen marked deflection of the septum *without* difficulty of breathing.

Dr. Sajous, of Philadelphia, thought that traumatism as a cause could not be clearly defined.

Dr. Mackenzie, of Baltimore, had not seen a case of deflected septum in the African that required an operation. He regarded *traumatism* as the most prolific cause. He also had been surprised at the brilliant results said to attend some operations.

Dr. De Blois, of Boston, said that he had observed the nose of several pugilists and had been surprised to find that the septum was in the correct line, while the nose in general had been flattened and bruised with great severity and repeatedly. He thought that these cases could with propriety be regarded as traumatic.

Dr. Roe, of Rochester, spoke of several peculiar varieties of deflected septum, and particularly objected to the use of the punch in the treatment.

Dr. Ingals, of Chicago, had seen deflected septum in children two years of age, and he had also come to the conclusion that, unless the nasal bones were fractured or cartilages dislocated, deflection of the septum was not likely to follow traumatism.

The discussion was closed by Dr. Delavan.

Dr. Langmaid, of Boston, related the case and presented

A PIN THAT WAS REMOVED FROM THE LARYNX,

where it had been for two years. It was sticking through the ventricular band and pointing backward.

Dr. Knight, of Boston, had seen the case, and spoke of its peculiar interest.

Dr. Solis-Cohen, of Philadelphia, mentioned what he had noticed for some time in ordinary examinations, and that was what appeared to be

A MUSCLE EXTENDING FROM THE OPENING OF THE EUSTACHIAN TUBE

across upon each side.

Dr. Rufus P. Lincoln, of New York, read the report of a case of

RECURRENT NASO-PHARYNGEAL TUMOR,

which he had cured by electrolysis. He used a single needle, and made sixteen applications in from four to six days. The growth had not shown any tendency to return.

The paper was discussed by Drs. Delavan, of New York; Langmaid, of Boston; Glasgow, of St. Louis; Solis-Cohen, of Philadelphia; and Hooper, of Boston, who spoke in commendation of this procedure in preference to the more formidable surgical operation, in cases diagnosticated early.

Dr. W. C. Jarvis, of New York, read a paper in which he reported

TWO CASES OF CONGENITAL OCCLUSION OF THE ANTERIOR NARES.

This is a rare condition. He had been unable to find a case recorded in medical literature, and the two reported were the only cases which he had met with in several thousand patients examined at his clinics. They were treated by means of his nasal drills and electromotor. In one case the obstruction was fibrous, and in the other osseous, and the results of treatment were very satisfactory.

Afternoon Session.

Dr. Alexander W. MacCoy, of Philadelphia, gave an abstract of his paper on

A COMPARATIVE STUDY OF SOME OF THE METHODS OF TREATMENT BEST ADAPTED TO THE RELIEF OF OCCLUSION OF THE POSTERIOR NARES

due to hypertrophy of soft parts, and not bony occlusion of the posterior nares, which he had never seen. He referred to different methods, and the difficulties which had been offered in way of reaching the posterior nares, and lack of precision in making applications. Since the advent of cocaine these difficulties, to a certain extent, had been overcome, but the effect produced by the drug rendered comparatively useless certain instruments which heretofore had been used satisfactorily; for instance, Jarvis' snare, the use of which he had ceased, except for the removal of nasal polypi, etc. From the fact that cocaine caused such retraction of the tissues, he had not been able to make use of the needle recommended by Jarvis; but, at the same time, the drug had brought into greater use the galvano-cautery and chromic acid.

The chief point in the paper was to present the superior advantage offered by a concealed flexible instrument for applying fused chromic acid. He preferred this to all other methods for removing these posterior hypertrophies.

Dr. Jarvis, of New York, regarded his transfixion needle as one of the most serviceable instruments he used for the removal of hypertrophied nasal tissue. He never used cocaine as a preliminary step, but first included the hypertrophy within the loop, drew the wire home, and

then applied the cocaine. He regarded chromic acid as dangerous and likely to be followed by unpleasant results. He never thinks of attempting to remove a hypertrophy by means of the galvano-cautery.

Dr. Rice, of New York, said that it was often difficult to remove these hypertrophies. He had given up the use of the transfixion needles. There were cases in which it was difficult to apply the loop posteriorly. He had never met with the disadvantages in the use of chromic acid spoken of by Dr. Jarvis.

Dr. Donaldson, of Baltimore, favored the use of chromic acid, as did his father, who had used it without bad results for many years. As to the needles, technical skill was required for their use, and in one case he had profuse hemorrhage following their use.

Dr. Delavan, of New York, had used chromic acid, discarded it, used it again, and had again discarded it. As for hemorrhage, he had not seen a case where it could not be controlled readily, and he believed that, practically, there was no danger from it.

Dr. Jarvis said that an attempt to remove a posterior hypertrophy, while a deflected septum existed, was very poor surgery. First remove the deflected septum, and the hypertrophy will disappear of itself. He regarded it as trifling with the patient's nostrils to use chromic acid when the hypertrophied tissue can be removed so easily with the transfixion needles.

The discussion was closed by Dr. MacCoy, who said that he had never been able to reach the posterior face of the middle turbinated bone before his little instrument was invented. A single application of chromic acid was, as a rule, all that was required. In comparison with it, he regarded the use of the needle as a very difficult operation. He never uses chromic acid without immediately antagonizing it.

Dr. Jarvis remarked that the fault was not in the needle but in the operator, who failed to make the few simple manipulations necessary to its successful use.

The paper by Dr. J. W. Robertson, of Detroit, on

PLASTER-OF-PARIS DRESSING FOR FRACTURE OF THE NOSE,

was read by title.

Dr. De Blois, of Boston, exhibited a plaster-of-Paris splint which he had used with good result in one case of fractured nose.

Dr. Jarvis explained his external splint, which he uses after operating on the cartilages and bones in certain cases of deflected septum, and thought it might answer a good purpose in cases of fracture.

Dr. Roe, of Rochester, exhibited a nasal saw which was operated by means of an electro-motor.

The Association then went into executive session.

A Dakota Doctor.—The Board of Health of Dakota publishes the results of an examination of an applicant for a license to practise medicine. He had been practising medicine for years in a populous district of South Dakota. Here are some questions and answers: Question. What medical journal do you take, doctor? Answer. Well, they have all run out. Q. Don't you intend to take any of them again? A. Well, I can get along without them. Q. What books have you in your library? A. "Gunn's Family Physician and Common Sense Home Doctor." Q. What is an element, doctor? A. Oh! anything. Q. Is that bed an element? A. Yes. Q. Name the three great cavities of the body. A. The head, the belly, and the diaphragm. Q. Mention the contents of the cranium. A. The brain and three skins. Q. Name contents of abdominal cavity. A. Kidneys and the prostate gland. Q. Does the prostate gland ever become enlarged? A. Yes. Q. Have you treated any cases of enlarged prostate? A. Lots of them. Q. With what success? A. Tip-top! Never lost a case. Q. Did you ever treat any female for enlarged prostate? A. Oh, yes; numbers of them.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 23, 1887.

Laurence Johnson, M.D., President, in the Chair.

Dr. Ralph L. Parsons read a paper, entitled

THE CLASSIFICATION OF MENTAL DISEASES; WITH THE SUGGESTION OF A COMPREHENSIVE METHOD DESIGNED TO HARMONIZE WITH AND HARMONIZE OTHER METHODS.

After reviewing the bases of the classifications which have been published by different writers, Dr. Parsons offered what he called a method, based upon symptomatology and etiology, for which he claimed the following advantages:

First.—It was a method so elastic and comprehensive that in it any variety of insanity which could be differentiated might be included, and all varieties and subvarieties could be reduced to a few fundamental conditions.

Second.—It includes all other systems in vogue.

Third.—It includes as many of the related facts as possible.

Fourth.—It has arranged, in tabular form, every variety of insanity, for comparison and for statistical purposes.

The four great divisions made were oligomania (monomania or paranoia), mania, melancholia, and dementia.

Dr. C. L. Dana spoke of the great difficulty that had been experienced in making a satisfactory classification of insanity, and he thought that the profession was indebted to Dr. Parsons for his endeavor to harmonize different views. Practically, he had adopted the classification of Skae, enlarged by Clouston, and modified by Kellogg; a system based partly upon etiology and partly upon symptoms. He regarded Dr. Parsons' classification as practically the same thing, and he was pleased to see that the author of the paper had independently brought forward the classification which was the most practical for working purposes, and had ingeniously combined other classifications in a more practical manner than he had yet seen. Dr. Dana, however, was very loath to leave out of any classification the degenerative types. As to the term "oligomania," he had already expressed a doubt as to the propriety of introducing a new term, although the term itself might not be specially objectionable.

Dr. Leszynsky spoke of the convenience of Dr. Parsons' method for practical purposes, arranged, as it was, for ready comparisons, and assignment of cases to the class in which they belonged.

Dr. Parsons remarked that, however good Skae's system might be, it was so imperfect that it was practically useless, and that Clouston did not follow it. If it were possible to apply the system, he would be ready to regard it as the best. All that he had attempted in his method was to so combine the different classifications as to make them as useful as might be.

THE DEATH OF DR. E. D. HUDSON, AND THE COMMITTEE ON ETHICS.

The President announced the death of Dr. E. Darwin Hudson. By his death a vacancy was created in the Committee on Ethics, of which he was the Chairman. The President appointed Dr. Alexander S. Hunter to fill the vacancy as *Chairman*, and Dr. C. E. Billington to fill the vacancy created in the Committee.

The Society then adjourned, to meet on the fourth Monday in September.

Sugar from Fat.—Seegen has recently shown experimentally that the liver can make sugar out of fat, and that, as a nutritive, fat is twice as valuable as sugar.

LUNACY LAW—CONGENITAL DISLOCATION OF THE HIP—A CLAMP FOR THE LINGUAL ARTERY—SURGERY AND RENAL SARCOMA—MALARIA AND POLITICS—DEATH OF DR. ALFRED MEADOWS.

LONDON, April 23, 1887.

Two recent occurrences have once more drawn attention to the unpleasant state of our present lunacy law. One of these is the bankruptcy of a medical man, bearing a well-known name, who had been involved in a long course of litigation in connection with the case of the now notorious Mrs. Weldon. No *mala fides* was alleged against him, but for signing (in conjunction with another medical man) a certificate whereby the lady in question was removed to an asylum and detained for a short time when not really insane, a jury mulcted him in a thousand pounds damages and costs. The *finale* to this is his appearance in a bankruptcy court, owing to his inability to pay the amount for which he has become liable. A somewhat similar case occurred very recently at the West End, but here the doctor was more fortunate in the matter of law. On regaining her liberty the patient prosecuted her doctor, but was non-suited, and judgment entered in favor of the doctor with costs. It was clearly established that, whatever might be the mental state of the patient at the time of the trial, she was, when incarcerated, plainly insane. Although nominally successful, the doctor, however, made a heavy pecuniary loss, for the patient, on losing the action, professed herself a pauper, and declared her inability to pay the costs. Such cases as these are enough to make doctors refuse to certify insane patients at any price. It is hoped that provision may be shortly made to remove by legislation such anomalies as the above. Several lunacy bills have been drafted within the last few years. That brought forward now seems to have some chance of being piloted successfully through the various dangers that beset it and of becoming law.

The last meeting of the Pathological Society was devoted almost entirely to the subject of congenital dislocation of the hip. Several specimens were shown, and their clinical histories narrated. At the Medical Society Mr. Lockwood read a paper on "A Method of Restraining Hemorrhage during Operations on the Tongue." Forceps were exhibited which he had devised with a view of compressing the lingual artery. One blade passed by the side of the tongue into the pharynx. The other was fitted to the outside of the lower jaw and met the other blade near the greater cornu of the hyoid bone, the artery being thus gripped between them. Dr. Money read a paper on the "Possibility of Surgically Treating Renal Sarcoma Occurring in Infancy." He thought there might be a chance for surgical treatment if the tumor were detected when very small. This could rarely be done, and in every one of the four cases he had observed the first clinical sign was enlargement of the abdomen. The prospect of being able to apply surgical treatment with advantage was, therefore, not very hopeful.

In Mr. North's lecture on "Malarial Fever," delivered at the London Institution on Monday last, he dwelt at some length on the relations of malaria to climate. It was pointed out that politics, as well as physical geography, had had something to do with the production of the present condition of the Roman Campagna. We had historical evidence that many localities now so malarious as to be uninhabitable were formerly highly esteemed by the Romans as health resorts. The invasions of the Goths depopulated these places and led to the development of malaria in districts where it had formerly been kept under control by human toil in cultivating the district. Mr. North referred to the recklessness displayed of late years in the cutting down of timber in the elevated districts as contributing toward the development of malaria in the lowlands. The removal of trees caused mountain streams to become uncontrollable, and thus led to the conversion of large areas of the lowlands into bog and swamp.

One by one the best known names in medical London are disappearing by death, and another generation is springing up to supply their place. The latest loss by death among men of note is that of Dr. Alfred Meadows, Obstetric Physician in St. Mary's Hospital, who died almost suddenly a few days since. He was well known as an obstetrician, and held numerous appointments. He was educated at King's College, and was for a short time Assistant Obstetric Physician to King's College Hospital, a position he subsequently relinquished to join the staff of St. Mary's Hospital. It is, of course, quite exceptional for a physician or surgeon who has become connected with one medical school to leave it for another. Now and then this occurs. One living obstetrician (Dr. Robert Barnes) has been connected successively with three out of the eleven medical schools in London, viz.: The London, St. Thomas', and St. George's Hospitals. Dr. Meadows was lately President of the British Gynecological Society, and the author of several works of repute, including a useful "Manual of Midwifery," which reached a fifth edition. At the time of his death he was in the enjoyment of a large and lucrative practice.

OUR PARIS LETTER.

(From our Special Correspondent.)

MORPHINOMANIA.

PARIS, April 22, 1887.

DR. OSCAR JENNINGS, one of the English practitioners of Paris, has had peculiar opportunities for studying the comparatively new disease termed morphinomania, and he has committed his observations to paper, which he communicated through Professor Ball to the Paris Academy of Medicine at one of its recent meetings. The paper was premised by the following remarks: "Among the numerous phenomena which result from the introduction of morphine into the economy by hypodermatic injections, there is one which has not been noticed by authors on the subject, and that is the state of the pulse, which offers at the same time a means of diagnosis, an indication relative to the treatment, and a rational explanation of some of the effects produced by this poison." The pulse, studied in the subjects of this disease by the aid of the sphygmograph, presents three different phenomena. During the state of "satisfaction," when the subject is still under the influence of a recent injection, the pulse is sensibly normal, but with a slight increase of tension at the end of the systole. When, on the contrary, the subject is in a state characterized by an irresistible desire to return to his habitual stimulant, the sphygmographic tracing of the pulse presents a "plateau" most characteristic—the portion of the curve which corresponds to the systolic impulsion is absolutely truncated. When the patient has been deprived of morphia for several days a febrile condition is produced, the body temperature rising to as much as 101° F., when the amplitude of the systole reappears. The "plateau" above referred to is an index of the feebleness of the cardiac impulsion, and this state of the circulation explains the feeling of faintness which so profoundly troubles the minds of the patients, and it is in these conditions that the *want* of the habitual stimulant is aroused which essentially constitutes the malady. In patients who conceal their vice, the presence of this "plateau" in a sphygmographic tracing constitutes an infallible element of diagnosis. It is known that morphinomaniacs, deprived of their habitual stimulant, return to their normal condition after a struggle more or less difficult and more or less pro-

longed. The problem to resolve consists therefore in suppressing the habitual stimulant and replacing it, at the moment when the want is felt, by a drug capable of arousing the activity of the circulation, and of restoring to the tissues the aliments indispensable to them. Various drugs have been vaunted as substitutes for morphia: Alcohol, coffee, paraldehyde, cocaine, apomorphine, chloral, vaniline, pilocarpine. But the greater part of these drugs have been found not only insufficient, but hurtful. They produce troubles peculiar to them and which often add to the inconveniences of morphia, without in any measure attenuating them. The authors thought that cardiac tonics were clearly indicated. With this view they had recourse to the sulphate of sparteine administered hypodermatically, which they did at the moment where the feebleness of the heart was indicated by the plateau of the sphygmographic tracing as well as by the inmost sensations of the patient. An injection of from two to four centigrammes was employed at this moment, which may be repeated if necessary, and in a few minutes the pulse was observed to be raised and the feeling of depression to disappear. The authors sum up the treatment of morphinomania as follows: 1. The patient should be removed from his own home and placed under the strict supervision of a physician. 2. The use of morphia should be more or less completely suppressed. 3. The action of the heart should be raised at the moment of depression, by an injection of sparteine, to which may be added, if necessary, an injection of morphia. Nitro-glycerine has also been administered in the form of a few drops placed on the tongue. Its effects are analogous to those of sparteine, but are much more rapid and much more ephemeral. The authors have obtained in a few weeks the best results from the above treatment, and if the patient is not completely cured, he or she is at least relieved of the imperious desire to return to his or her former habits.

I have spoken of the authors in the plural number, as the above paper was written conjointly by Drs. Ball and Jennings. Dr. Jennings, however, has developed the subject and published it in the form of a pamphlet, in which he gives some cases in detail, and makes some interesting observations on the pathology and treatment of this most intractable malady. In the treatment I find that the author extols valerian and soda, though he does not explain their mode of action in morphinomania. Dr. Jennings dwells upon the absolute necessity of the morphinomaniac being separated from his intimate relations and friends, and that he should be placed under the care of strangers, who would be in a better position to carry out the injunctions of the medical attendant; but the almost *sine qua non* for the cure is, according to the author, the *will* of the patient—that is to say, his determination to get well—without which all the efforts on his part and on that of the physician would prove of little or no avail.

At the instigation of Dr. Roussel, of Geneva, who extols the use of eucalyptol hypodermatically in the treatment of pulmonary phthisis as an effectual means of reaching the bacilli in the lungs, Professor Ball tried the remedy in his hospital, with the following results: Of 21 patients who were submitted to this treatment, 6 died, 10 were improved and left the hospital, and 5 were still under treatment on the date of the communication made by him to the Academy of Medicine. Dr. Ball remarks that one of the latter patients, whose sputa had been charged with tubercular bacilli, presented none on that day. The mode of operation adopted by Dr. Roussel consists in injecting hypodermatically one gramme of a solution composed of eucalyptol dissolved in two volumes of olive-oil, which is performed in the thickness of the skin by the side of the mouth. But Dr. Dujardin-Beaumetz, who experimented with this mode of treatment, declared at a subsequent meeting of the Academy that the results dotained by him differed from those announced by Dr. Ball. He had never observed the disappearance of the bacilli. It is true that eucalyptol diminishes the expectoration, but then the patients suffer from great oppression. Moreover, the exhalation of this substance from the lungs disgusts the patient and takes away his appetite. In fine, this treatment presents more inconveniences than advantages.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 29 to June 4, 1887.

FRYER, B. E., Major and Surgeon. Granted two months leave on account of sickness, permission to apply for an extension. S. O. 28, Division of the Pacific, May 28, 1887.

BROWN, PAUL R., Captain and Assistant Surgeon. Granted leave of absence for four months. S. O. 126, A. G. O., June 2, 1887.

PERLEY, H. O., Captain and Assistant Surgeon. Relieved from duty at Fort Maginnis, M. T., and ordered for temporary duty at Fort Snelling, Minn. S. O. 49, Department of Dakota, May 23, 1887.

WOOD, LEONARD, First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Fort Huachuca, A. T. Relieved from duty at Headquarters, Department of Arizona. S. O. 126, A. G. O., June 2, 1887.

SUTER, WILLIAM N., First Lieutenant and Assistant Surgeon (recently appointed). Ordered for temporary duty at Washington Barracks, D. C. S. O. 122, A. G. O., May 27, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending June 4, 1887.

BRANSFORD, JOHN F., Surgeon. Ordered to the Smithsonian Institution at Washington, D. C.

TRYON, J. RUFUS, Surgeon. Detached from the U. S. S. Quinnebaug and ordered home.

SIEGFRIED, CHARLES A., Surgeon. Ordered to the U. S. S. Quinnebaug.

MARTIN, WILLIAM, Assistant Surgeon. Detached from the U. S. S. Pinta and ordered home.

FITTS, HENRY B., Passed Assistant Surgeon. Detached from the Receiving Ship Vermont and ordered to the U. S. S. Pinta.

FIELD, JAMES G., Assistant Surgeon. Ordered to the Receiving Ship Vermont.

Original Articles.

INTUBATION.[1]

By FRANCIS HUBER, M.D.,

CLINICAL ASSISTANT OF DISEASES OF CHILDREN AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

In the treatment of laryngeal stenoses depending upon the presence of pseudo-membrane (the symptoms being sufficiently well marked to warrant operative interference), the laryngeal brush, sponge, probang, and forceps; catheterization of larynx, tubage, intubation, and tracheotomy have been employed to relieve the urgent dyspnœa. The brush, probang, and forceps are but temporary expedients intended to remove loose membrane, and afford relief for the time being. Catheterization, tubage, and intubation, while facilitating the expectoration of membrane, are resorted to primarily for the purpose of relieving the dyspnœa, the immediate source of danger in the severer forms of pseudo-membranous or diphtheritic laryngitis. Tracheotomy, it is true, relieves the dyspnœa, but, for reasons apparent later on, I would advise the operation in those instances only in which intubation fails. In view of the results reported thus far such cases, I venture to predict, will be exceptional.

The brush, probang, and forceps are not often used at present. Catheterization is an infrequent procedure, and has not served its purpose as well as was anticipated. Tubage, injudiciously advocated by Bouchut and condemned by Trousseau, soon fell into disuse. In a number of text-books it is referred to in a contemptuous way and dismissed in a few words.

To quote from Pepper's "System of Medicine" (vol. iii., page 107): "Tubage was rendered ridiculous at once by the assertion of Bouchut (1858), that children suffering from croup, who were supplied by the laryngeal tube, were not only relieved at once, but expressed their gratitude in audible oratory. Still there are some cases of more recent date in which tubage is reported to have been attended with success. It is not very probable, however, that a larynx which admits of no air, because of its being clogged with firm pseudo-membrane, should be willing to admit and endure the presence of a tube." Such was the almost universal teaching up to within a short time. Physiology, theory, and practice were against the new method. To-day, however, the author of the quotation referred to above, whose name is familiar over the two continents, a strong advocate of tracheotomy, and who has performed more tracheotomies than any six American surgeons, and with the average success, proclaims himself a convert to intubation, and teaches its advantages in his clinical lectures. Recently, before the State Medical Society, he has publicly discarded the opinion expressed above, and states that a large number of children have been relieved immediately, not only temporarily, but permanently, by intubation.

Unphysiological, ridiculous, improbable, impracticable, and dangerous as the procedure may appear to those not practically familiar with the measure, hundreds of cases in the practice of various independent observers have demonstrated the practicability, utility, and advantages of intubation as originated and practised by Dr. Joseph O'Dwyer, of New York. The dyspnœa is as effectually removed in intubation as after a tracheotomy, and though the children may not thank you, the ability to speak is maintained, and the little one can express his or her wants in "audible oratory." The marked and almost instantaneous change in the appearance and condition, the quiet sleep and quiet respiration, the absence of any external wound, shock, and other evidences of an operation more or less prolonged and difficult, impress one more forcibly than thanks. The whisper of a patient with an O'Dwyer tube in his larynx, rescued, in an incredibly short time from impending suffocation, by intubation, is more agreeable to the parents and physician than the loud tracheal breathing of a child wearing a tracheotomy tube, unable to express its wants or sensations by the least sound. I have frequently seen little patients, upon whom a tracheotomy had been performed, not able to make their attendants understand their wants, become restless, excited, and miserable, until, perhaps after the lapse of a few moments, after considerable guessing, first showing one article, then another, asking question after question of the speechless little sufferers and watching the face for an answer—finally, more by chance than otherwise, quiet down at last, when they had made themselves understood by a nod or motion, as the desired object was brought or want was gratified.

That the larynx will tolerate a tube has been demonstrated repeatedly and beyond question. The sensitive organ which rebels when a crumb of bread or a few drops of water go the "wrong way" in swallowing tolerates the tube, not for a few seconds or minutes, but for days and even weeks. The intubation-tube does not act the part of a foreign body, the presence of which excites and irritates the laryngeal orifice; the passage, so to speak, has been forced, and the tube rests within the box of the larynx and trachea and is covered by the epiglottis—rests there quietly, without exciting any reflex action or spasm. We are aware of its presence objectively by the unobstructed respiration and the full, explosive, metallic, characteristic cough induced by swallowing liquids.

Bichat reports that Dessanet, in 1801, accidentally demonstrated the fact that the larynx and trachea would tolerate a tube. This knowledge he put to good use, and, in a case of œdema of the glottis, he allowed a catheter to remain for one and a half day, the patient recovering. In 1854 Horace Green announced that he could swab out the trachea and pass a flexible tube into either bronchus, and thus inject strong solutions of nitrate of silver into tuberculous cavities. Trousseau, in his article on the "Treatment of Diphtheria and Croup," discusses catheterism of the larynx, states that Dieffenbach had practised it in 1839, speaks disparagingly of Green's method, and lauds the plan proposed by Loiseau. The latter "arms the first two phalanges of the index-finger with a bent metallic finger-stall, which leaves free the last joint and the distal phalanx. The finger thus protected is carried down into the throat as deep as possible, and with the extremity of the finger the epiglottis is raised. This being accomplished, nothing is easier than to introduce an instrument into the larynx."

In a case of œdema of the glottis Hack employed one of Schroetter's bougies. The tube was removed and the patient sent to the hospital. On the way, being attacked with severe dyspnœa, the man introduced the tube into his own larynx.

[1] Read before the New York Academy of Medicine, June 2, 1887.

McEwen (*British Medical Journal*, July 24, 31, 1880) has shown that a catheter or tube, introduced through the mouth, may be employed as a substitute for tracheotomy or laryngotomy in case of disease or operation. Monti, of Vienna, has for years made use of hard-rubber tubes, introducing them into the larynx and allowing them to remain *in situ* twenty-four hours or more. One end protrudes from the mouth; they are resorted to as temporary expedients, made use of only until tracheotomy can be performed.

Stockton, of Chicago (*Jour. Am. Med. Assoc.*, May 2, 1885), employed silver tubes of various shapes, with and without flanges, but soon discontinued his experiments. Weinlechner, Monti (referred to above), and Schroetter have employed catheters to provide an artificial aperture in croup. Recently, catheterization of the trachea and bronchi has been revived by Reichert and others, and various applications made directly to the sub-laryngeal air-passages, the parts being anæsthetized by cocaine.

Dr. Landgraf (assistant at Professor Gerhardt's clinic) catheterized the left bronchus (man, aged fifty-two years) several times weekly, cocaine being applied to the trachea and larynx, and succeeded in passing an obstruction eleven inches down, caused by the presence of an aortic aneurism. The relief to the dyspnœa and distressing cough was enormous. To enter the domain of laryngeal surgery proper, and quote instances which exemplify the tolerance of the larynx to instrumental interference would lead me too far.

In September, 1858, Bouchut read a paper before the Academy of Medicine (Paris), entitled "A new Method of Treatment of Croup by Tubage of the Larynx." His conclusions were, briefly:

1. Tubage is easily accomplished by means of a cannula fastened upon the inferior vocal cords, without interfering with the functions of the epiglottis.
2. The tolerance of the cannula by the larynx.
3. The possibility of relieving the dyspnœa of croup and other laryngeal affections without tracheotomy.
4. The facility with which the membrane is expelled through the tube.
5. The advantages of tubage to the country practitioner far from assistance, etc.

Trousseau, as chairman of the commission appointed to investigate the subject, reported as follows:

Tubage of the larynx in certain cases of acute laryngitis can, by retarding asphyxia, prove of curative value.

In certain chronic diseases of the larynx it will allow one to delay tracheotomy, and sometimes relieve and cure the patient.

In the treatment of croup it delays asphyxia and allows a more easy introduction of air and agents capable of modifying the diphtheritic inflammation.

It can only very rarely supplant tracheotomy, which is the principal means of opposing croup when medical measures fail.

Ridiculed and condemned as unphysiological and impracticable by Trousseau, it fell into disuse and was soon forgotten.

Without any prior knowledge of what had been done, Dr. Joseph O'Dwyer, after a great many experiments, rediscovered intubation, and has since completely vindicated the position taken by Bouchut. The instruments devised and perfected by O'Dwyer are in no respects like those employed by the French physician. The tubes of Bouchut were hollow cylinders, narrower at one end and less than an inch long; they rested upon the vocal cords and did not reach into the trachea. A thread was left attached and was brought out at the angle of the mouth, to facilitate removal and prevent them being swallowed.

The instruments of O'Dwyer have passed through successive stages of evolution, and are too well known to require any extended description.

The number on the scale (Fig. 3) indicates the years for which the corresponding tubes are suitable. For instance: The smallest tube, when applied to the scale, will reach to the first line, marked 1, and is intended to be used up to the age of twelve or fifteen months; the size marked 2 is suitable for the next year; 3 and 4 for these years, and so on. When the proper tube is selected for the case to be operated on, a fine thread is passed through the small hole near its anterior angle, and left long enough to hang out of the mouth; its object being to remove the tube, should it be found to have passed into the œsophagus instead of the larynx.

The obturator is then screwed tightly to the introductor, to prevent the possibility of its rotating while being inserted and passing into the tube; the groove in the upper extremity of the obturator being made to correspond to the small hole in the tube intended for the string.

Fig. 4.

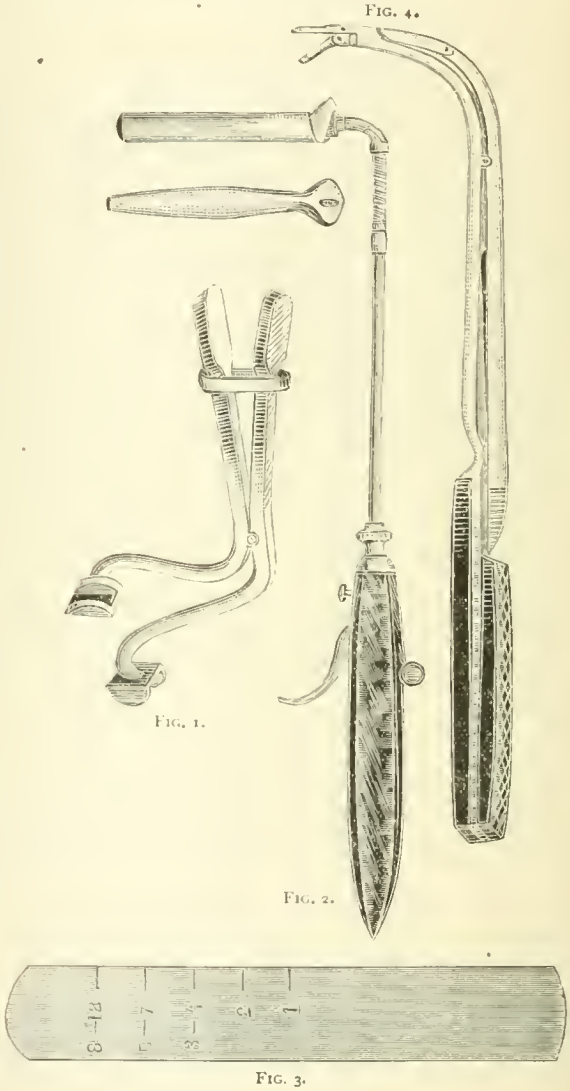

Fig. 1.

Fig. 2.

Fig. 3.

The following is the method of introducing the tube, which is done without the use of an anæsthetic: The child is held upright in the arms of a nurse, and the gag (Fig. 1) inserted in the left angle of the mouth, well back between the teeth, and opened widely; an assistant holds the head, thrown somewhat backward, while the operator inserts the index-finger of the left hand, to elevate the epiglottis and direct the tube into the larynx.

The handle of the introductor (Fig. 2) is held close to the patient's chest in the beginning of the operation, and rapidly elevated as the cannula approaches the glottis. The tube is then pushed downward, without using much force. It is then detached. The joint in the shank of the obturator is for the purpose of facilitating this part of the operation. As soon as the obturator is removed, and it is ascertained that the tube is in the larynx, the

thread is withdrawn, but at the same time the finger is kept in contact with the tube, to prevent its being also withdrawn.

It is important that the attempt at introduction be made quickly, as respiration is practically suspended from the time that the finger enters the larynx until the obturator is removed. It is, therefore, under the circumstances, much safer to make several abortive attempts than one prolonged effort, even if successful.

For the purpose of removal, the patient is held in a similar position, except that the head is not inclined backward, or very slighly so, and the extractor is passed into the tube, guided by the index-finger of the left hand, which also fixes the epiglottis, and is brought in contact with the head of the cannula. Firm pressure with the thumb is then made on the lever above the handle, while the tube is being withdrawn. If secondary dyspnœa supervenes at any time the tube should be removed and a larger one substituted. If the case progresses favorably, the tube should be removed on or about the fifth day.

To avoid accidents, it is very essential to have some preliminary practice on the cadaver, particularly in extracting, which is the more difficult operation, owing to the aperture of the tube being so much smaller than that of the larynx.

In very young children particularly, extraction is facilitated by pushing the larynx upward and backward with the thumb of the left hand externally, the index-finger being in contact with the head of the tube. In the absence of a cadaver, it has been suggested to practise intubation upon dogs anæsthetized.[1]

In introducing or extracting, the instruments should be worked in the median line, the operator facing the patient squarely.

Waxham advises that in introducing or extracting, the point of the instrument should be placed under the finger, not over or alongside.

Dr. Cheatham, of Louisville, suggests that inversion of patient, or inversion with sharp blow on the back or irritating the soft palate or pharynx, may be tried in in order to remove the tube. We recognize that the tube has been successfully introduced: 1, By the occurrence of a paroxysm of coughing; 2, by the relief of the dyspnœa. The cough is full, explosive, characteristic, and accompanied by the expectoration of large quantities of mucus and shreds of membrane.

Intubation has passed the experimental stage. It has been performed hundreds of times by O'Dwyer, Dillon, Brown, and Waxham.

Northrup and Denhard have also done it in quite a large number of cases. The procedure is extensively employed in New York, Chicago, and Philadelphia, and though not as yet an established method, it has a good record and a great future.

The above list does not represent all the cases of croup treated, but only those in which operative interference was indicated. In my own practice I have not found it necessary to resort to intubation in a larger proportion than one out of three or four cases of laryngeal stenosis treated from the onset. I will say, and would emphasize the assertion, that intubation should not be resorted to until the stenosis assumes a dangerous character and the case, if seen sufficiently early, has not been benefited by proper medicinal means. I am well aware of the truth of the statement made by Thomas: "There is nothing easier than the rejection of the testimony of others and the discrediting of the deductions which we ourselves have not drawn" ("Diseases of Women," p. 458). The instances of recovery which I report above were cases which, in the opinion of the various gentlemen present at the time, would have terminated fatally if the obstruction to respiration had not been removed. The cases were similar in severity to those in which, up to a year ago, I advocated, and would have performed, tracheotomy.

Before entering upon a consideration of the accidents, mishaps, and objections to the process, I shall devote a few words to the diagnosis of croup and the indications for operative interference. When called to a case, assure yourself that the dyspnœa is of laryngeal origin. Examine the neck and chest carefully. Inattention to this point has occasioned some grave errors. In one case the removal of a mass of poultices and bandages from the neck revealed a large abscess in front of the larynx, incision of which, with the insertion of a drainage-tube, caused the disappearance of the laryngeal symptoms. In a second case a child, sixteen months old, with hoarseness and difficulty of breathing, was referred to me with the diagnosis of croup. A careful examination of the chest revealed a large empyema. Several cases are known to me in which retro-pharyngeal abscesses have been mistaken for croup.

The diagnostic symptoms of membranous obstruction are croupy cough, aphonia, croupy inspiration and expiration, with progressive, unremitting dyspnœa, marked supra-sternal and epigastric retraction, and continued restlessness. Auscultating the chest posteriorly, we find the normal vesicular murmur feeble or absent. Finally, cyanosis occurs, with feeble and irregular pulse. The temperature, unless there be septic absorption from diphtheritic deposits in the nose or pharynx, or some inflammatory complication in the chest, will not exceed 100° or 101°. "One of the pathognomonic symptoms of diphtheritic laryngitis, 'membranous croup,' is the relative absence of fever." "Catarrhal laryngitis, pseudo-croup, is a feverish disease. A sudden attack of 'croup,' with high temperature, provided there is no pharyngeal or other diphtheria present, yields a good prognosis; without much fever a very doubtful one." "In œdema of the ary-epiglottic folds and post-attachments of the vocal cords, with or without membranous deposits elsewhere, we have the symptoms of true croup with its dangers. Inspiration is impeded, owing to the partial paralysis of the vocal cords; expiration, however, is free, and the voice is more or less intact. Diagnosis may be made by palpation. Aphonia, with difficulty of breathing in both inspiration and expiration, points positively to membranous occlusion" (Jacobi).

True croup, as it progresses, presents a picture "the likes of which the most hardened man, the most experienced medical attendant, prays never to behold again." To relieve the sufferings and struggle of the little patient for air intubation has been proposed. And now, *when* shall we resort to operative interference? As soon as the supra-sternal and epigastric retraction is marked, when there is great and continued restlessness owing to the progressive severe dyspnœa, and the normal vesicular murmur is feeble or absent at the posterior inferior portion of the lung, we ought to intubate. Cyanosis, with a feeble and irregular pulse, pulmonary complications, or septic manifestations, ought not to deter one from intubating, even in instances apparently hopeless. It is well, however, to give a hypodermic of brandy, caffein, etc., before operating in these desperate cases.

My own cases up to the present, numbering 47, are presented in a tabulated form for convenience and ready reference.

Accidents, Mishaps, and Objections. — *Gag.*— O'Dwyer's gag may be displaced by struggles of child. Denhard's modification of above, not liable to this accident, should be employed. If heart's action weak or general condition poor, separation of jaws by gag may cause alarming symptoms of asphyxia due to falling back of tongue. In this condition give hypodermic of brandy, or caffein, or other cardiac stimulant before inserting gag—pull tongue forward.

Thread ought to be eighteen to twenty inches long, and if not removed at once, looped over the ear to pre-

[1] The finger ought to be educated and digital examinations made of epiglottes and adjoining parts in children suffering from throat-disorders.

vent its being swallowed. In a case reported by Dr. Hance, traction upon the string by the muscles of deglutition caused the tube to be pulled into the œsophagus and swallowed. In one of Dr. Agan's cases, the thread being swallowed, a bent probe was used to fish it up. In Dr. Schottky's case, the thread being too short, the tube, having slipped into the œsophagus, entered the stomach and was passed per anum two days later. (A second tube, after considerable difficulty, owing to the swollen condition of the parts, being placed in the larynx, child recovered.) Tipton (THE MEDICAL RECORD, May 28, 1887) reports that in wiping away some saliva the silken cord was caught, tube dragged out of larynx and swallowed, before the cord could be grasped. A second tube now introduced. First tube passed per rectum ten days later.

Tube.—(*a*) May enter the œsophagus, recognized by breathing not being improved and cough still croupy.

(*b*) Danger of delicate parts being lacerated; the rounded end of the obturator closes the lower portion of tube completely and prevents injury, unless force be employed.

(*c*) Membrane may be crowded down in front of tube. This is a possible and serious accident. When it occurs and the membrane is not expelled when the tube is removed, tracheotomy may be necessary. Dr. Ferguson reports a case in which he was compelled to perform tracheotomy (*N. Y. Med. Journal*, March 5, 1887). In other instances this resulted in death of patient.

Dr. Waxham has devised a trachea-forceps to remove the membrane through the mouth when this unfortunate accident has taken place. He reports a case in which the accident occurred and in which a cast of the trachea and main bronchi were removed by passing the long trachea-forceps through the mouth into the larynx and trachea, in a child seven years of age (*Medical News*, January 1, 1887). "The intubation-tube was now introduced; respiration so quiet as to be scarcely observed."

In an instance in which the accident occurred to me, I gave some pure brandy (hoping that some would enter trachea through tube and cause expulsion), thus inducing a severe paroxysm of coughing which expelled tube and a large piece of membrane. The tube was reintroduced; breathing unobstructed; child recovered. In Dr. Caillé's case removal of tube was followed by expulsion of membrane.

The lateral bulging weight of tube, together with the anatomical fit and length, tend to keep it from being coughed out.

1. *The tube may be coughed out* (*a*) by a severe paroxysm of coughing, (*b*) if too small, or (*c*) if a plug of mucus or membrane is below it. Not serious, as breathing is generally improved and dyspnœa will not return for several hours. This has been my experience. When dyspnœa returns tube can be reintroduced.

2. *May become occluded* by mucus or membrane. As the air is warm and moist and the inner surface of tube is smooth, mucus passes through tube readily. When tube becomes occluded with membrane the tube is coughed out in many instances. One case, however, is reported by Dr. Wheeler (*N. Y. Med. Journal*, February 26, 1887) in which plugging of tube caused death of child.[1]

3. Tube may *be coughed up and then swallowed.* Dr. Parkes refers to a case in a young lady, seventeen years of age, who passed tube per rectum twenty-four hours after intubation. In Dr. Montgomery's case it was feared that as a smaller tube than suited to age was inserted, the tube might have passed into trachea. A tracheotomy was done and child recovered. Intubation-tube passed per anum two days later (*Med. News*, March 5, 1887). It seems to me that the proper plan would have been to have inserted a second tube. Dr. S. Hemingway kindly gave me the details of a case in which, after a violent fit of coughing, hoarseness was again noticed (four days after tube had been inserted by Dr. O'Dwyer). A week later the tube was passed per rectum.

4. Tube may *descend into the trachea.* This accident has occurred several times. It must not be forgotten, however, that the tubes were of an earlier pattern (Waxham, Chicago *Medical Journal and Examiner*, November 25th; Eichberg, Cincinnati *Lancet and Clinic*).

The shape of the head, the resistant nature of the vocal cords, and length of tube prevent a repetition of the accident when the latest style of tubes are used.

Dr. Brothers, at my suggestion, has kindly made the following experiment in the dead-house: "The smallest-sized tube was introduced into the larynx of a child five years of age and an incision made in the trachea. Making traction below it was found that considerable force was required to pull the head of the tube below the vocal cords; it was impossible, however, to force it below the cricoid cartilage."

5. *Entrance of food into* bronchi and thus cause "schluck pneumonie." Discussed further on.

6. Cause ulcerations and possible hemorrhage. "The head or shoulder of tube does not rest upon the vocal cords, but just above them on the ventricular bands. There is not any ulceration of the cords, but slight ulceration may be produced by the head and lower end of the tube, when retained for a long time." This does no harm.

7. May give rise to difficulty in swallowing. Discussed further on.

8. Dr. Hance reports two cases in which there was sudden and complete cessation of respiration, due to excessive secretion of mucus and falling back of tongue, forcing epiglottis over the fenestra of the tube. Relief was afforded by depressing tongue and forcing it forward, in order to remove mucus from throat.

Accidents possible in extraction.—1. May be forced down into trachea. This occurred in Dr. Eichberg's case, the tube being of the old pattern, and necessitated tracheotomy for its removal. No danger of this accident with the latest style of tube.

2. Tube may be firmly fixed by swollen fold of mucous membrane of epiglottis or ary-epiglottic folds (œdematous); pushing it aside by finger made removal possible (Caillé). Similar condition found at autopsy in one of Dillon-Brown's cases (THE MEDICAL RECORD, April 10, 1886).

3. Possible aspiration of food into bronchi during vomiting while extraction is attempted. Occurred in one of my cases, the little patient having eaten a very hearty meal shortly before. Did no harm in this case. Would advise, however, that but little nourishment be allowed for several hours prior to extracting tube.

In extracting, try to sink the forceps deeply into the tube and thus secure a firm hold, otherwise they may slip as the handle of the extractor is carried downward. It is well, therefore, to keep the left index-finger in contact with the shoulder of the tube, so that its removal may be accomplished by the finger if the forceps slip after the tube has been raised out of the larynx (the child being inclined forward at same time).

Removal of tube.—1. The tube may be removed as early as the fourth, fifth, or sixth day; exceptionally it may be necessary to allow it to remain ten or eleven days. O'Dwyer's tube can be dispensed with much more readily and earlier than the tracheotomy-tube. This is due to the fact that more or less membrane is detached from the larynx when the tube is introduced.

2. The frequent forcible and explosive cough assists in dislodging and expelling mucus and shreds of membrane.

3. The presence of the tube must of necessity cause more or less disintegration of the false membrane with which it is in contact.

[1] The doctor states that "during the evening the child breathed noisily, as though there were a good deal of mucus in the tube, but apparently without any impediment to respiration. At 10 P.M. she had a severe fit of coughing, and, according to her mother's account, choked up and died in about two minutes."

The noisy breathing in the case is to me an indication to remove the tube temporarily. If this had been done the membrane no doubt would have followed removal of the tube, and the untoward result might have been avoided.

Table of Cases.

Case.	Age.	Diphtheritic patches on	Complications.	Degree of stenosis.	Tube removed.	Relief to dyspnœa.	Recovery.	Cause of death.	Operator.	Remarks.
1	1 year.	Tonsils and pharynx.	.....	Advanced.	....	Complete.	.....	Heart-failure 18 hours later.	Emergency call.	Tube coughed up; reintroduced.
2	2 years.	Fauces.	.....	"	.....	.....	.....	Sepsis 6 hours later.	Dr. Denhard assisting.	
3	2 yrs. 8 mos.	Nares and pharynx.	.....	"	7th day.	Complete.	Recovery.	.....	Drs. Neufield and Mauson.	
4	6 years.	Nares and tonsils.	Measles.	"	6th day.	"	"	. . ..	Dr. Neufield.	
5	3 yrs. 8 mos.	Nares and tonsils.	.....	"	.....	"	.....	3½ days later pneumonia and nephritis.	Dr. Denhard assisting.	Tonsils very large: intubation difficult in consequence.
6	3 years.	Tonsils and pharynx; membraneg ganrenous.	Measles.	"	.....	Partial.	.....	Uræmic convulsions 6 hours later.	Dr. Neufield.	
7	2 yrs. 2 mos.	Tonsils and pharynx.	. .....	"	6th day.	Complete.	Recovery.	.....	Dr. Neufield.	Child had eaten a hearty meal, and each attempt at removal of tube induced vomiting; fearing that food might enter larynx, I waited until stomach was empty and then removed tube without much trouble. Brandy and caffein injected.
8	3 years.	Nares and pharynx.	Old mitral endocarditis.	"	"	.....	".	.....	Drs. Neufield and Mauson.	Brandy and caffein were injected on account of weak and irregular pulse. As the patches had disappeared, tube removed on sixth day. Child comfortable. Two days later was called again (Dr. Denhard kindly seeing case with me), and found recurrence of stenosis; the ary-epiglottic folds felt swollen and rounder than normal. Again intubated, with immediate relief, and 3 days later tube removed, a pneumonia having developed in the meanwhile. Upon close questioning found that patient was allowed to sleep in a crib near the door, thus accounting for the laryngeal complication and the pneumonia. Two months later was presented at Dr. Jacobi's clinic.
9	2 yrs. 6 mos.	Tonsils and pharynx.	Measles.	"	5th day.	Complete.	.....	6 days afterward pulmonary œdema, secondary to Bright's disease.	Dr. Berlinger.	Comfortable until morning of fifth day, then rise of temperature, dulness at left apex, suppression of urine, and pulmonary œdema.
10	1 year.	Tonsils.	.....	"	Tube coughed up on 4th day.	"	Recovery.	.....	Dr. Horn assisting.	Case seen by Dr. Schlessinger, who confirmed diagnosis and regarded case as hopeless if operative measures were not resorted to.
11	2 yrs. 6 mos.	Nares and fauces.	.....	"	.....	Fair.	.....	4 hours later sepsis.	Dr. Schlessinger.	Child moribund when seen.
12	11 months.	Tonsils.	Measles two weeks before.	"	....	Complete.	Recovery.	.....	Dr. Denhard assisting.	
13	15 months.	Nares.	Measles and gastro-enteritis.	"	.....	"	.....	Exhaustion 12 hours later.	Dr. Wilson.	
14	18 months.	Nares and pharynx.	.....	"	.....	"	.....	Pneumonia 2½ days later.	Dr. V. Rottenburg.	
15	3 years.	No patches visible; membrane coughed up.	Measles a short time ago.	"	5th day.	"	Recovery.	.....	Dr. Lilienthal.	
16	4 years.	Tonsils and soft palate.	.....	"	"	"	"	.....	Dr. Brugman.	Tube coughed up; saw case 3 hours later with Dr. Denhard Symptoms of stenosis extreme. A larger tube (5–7 years) was then introduced and retained.
17	2 years.	Nares and pharynx.	.....	"	.....	"	.....	2½ days later pneumonia.	Emergency.	
18	3 years.	Nares and pharynx.	Hemiplegia.	"	.....	"	. ....	3 days later sepsis.	Dr. Naughton.	Child had had some brain trouble during the summer, resulting in left hemiplegia. General condition poor.
19	18 months.	Nares and pharynx.	.....	"	.....	"	.....	2 days later pneumonia.		
20	11 months.	Nares and pharynx.	.....	"	.....	"	.....	2 days later sepsis.		
21	2 yrs. 8 mos.	No patches visible; pieces of membrane coughed up later.	Measles one week ago; pneumonia present.	"	11th day.	"	Recovery.	.....	Dr. Denhard assisting.	Seen 3 days before intubated by Dr. Jacobi, and diagnosis of membranous laryngitis confirmed. Tube removed on sixth day, but necessary to reintroduce it 15 minutes later. Great difficulty in nourishing the patient; resorted to stomach-pump.
22	8 months.	Nares and pharynx.	Pneumonia.	"	.....	"	.....	18 hours later heart-failure.	Dr. V. Rottenburg.	
23	4 yrs. 6 mos.	Membrane coughed up.	Measles short time ago.	"	7th day.	"	Recovery.	.....	Dr. Denhard assisting.	This patient is a sister of Case 21.
24	2 yrs. 8 mos.	.....	Measles.	Marked.	Coughed out on 4th day.	"	.....	Died 36 hours after tube was coughed out; pneumonia.	Dr. Lyttle.	Dr. Lyttle writes that intubation was a success as far as the relief of the stenosis was concerned.
25	3 yrs. 6 mos.	Tonsils and pharynx.	.....	Advanced.	Coughed out on 6th day.	"	Recovery.	.....	Dr. Neufield.	Child not seen by Dr. Neufield until patient was nearly moribund. Injected brandy and caffein, and then intubated.
26	10½ months.	Tonsils, soft palate, and pharynx.	.....	"	4th day.	"	"	.....	Dr. Denhard assisting.	Pneumonia developed after 48 hours; temperature at highest, 105°; ran usual course, and patient recovered.
27	2 yrs. 10 mos.	Tonsils, pharynx, and soft palate.	.....	"	.....	"	.....	2 days later secondary croup.	Dr. Brothers assisting.	
28	3 years.	Membranes gangrenous.	Septic case.	"	.....	Partial.	.....	Sepsis.	Dr. J. Horn.	

TABLE OF CASES.—*Continued.*

Case.	Age.	Diphtheritic patches on	Complications.	Degree of stenosis.	Tube removed.	Relief to dyspnœa.	Recovery.	Cause of Death.	Operator.	Remarks.
29	4 yrs. 6 mos.	Tonsils and pharynx.	Pneumonia.	Advanced.	6th day.	Complete.	Recovery.	.....	Dr. F. Nordeman, Dr. Brothers assisting.	Prognosis extremely unfavorable in this case. Intubated, with a view to enthanasia.
30	2 years.	Membrane coughed up.	... .	"	.....	"	.....	. .....	Dr. J. Horn.	
31	11 months.	Membrane coughed up.	.	"	8th day.	"	Recovery.	. ...	Dr. Teschner.	An older child sick with laryngeal stenosis at same time, but symptoms were not sufficiently urgent to require intubation.
32	13 months.	Tonsils and palate.	Pneumonia.	"	.....	"	..	Exhaustion 2½ days after.	Dr. Neufield.	
33	9 months.	.....	Measles.	"	....	"	. ....	Exhaustion 6 hours after.	"	
34	2 yrs. 6 mos.	Nares.	Measles a week ago.	"	.... .	"	Recovery.	....	Dr. Brothers.	Tube removed on 5th day; 1 hour later Dr. Brothers reintubated because of recurrence of stenosis, using small tube; 36 hours later it was coughed up and not necessary to insert again.
35	7 years.	Tonsils and pharynx.	....	"	Coughed up after 64 hours.	"	"	... .	Dr. H. F. Nordeman.	Intubation easily accomplished. Shreds of membrane, etc., coughed up; still respiration is somewhat obstructed, and it was evident that membrane had been forced down. Tracheotomy not allowed, and no forceps accessible. Gave pure brandy (3j.), causing severe paroxysm of cough, with expulsion of tube and large piece of membrane. Intubated again; relief complete.
36	3 yrs. 6 mos.	Nares and pharynx.		"	... ..	"	. ..	Secondary croup 2 days later.	Dr. Neufield.	
37	18 months.	Membrane coughed up.	..	"	....	"	.....	Heart-failure 18 hours later.	Dr. Denhard assisting.	
38	18 months.	Nares and fauces.	.	"	Coughed up on 6th day.	"	.....	Convulsions 10 hours later.	Dr. D. Cook.	
39	9½ months.	No membrane visible: pieces coughed up.	....	"	Removed on 7th day.	"	Recovery.	....	Case of Dr. Neufield, Dr. Denhard present.	
40	2 yrs. 6 mos.	Tonsils.	. ..	"	. .. ..	"	"	.....	Drs. Bennett and Neufield.	
41	5 yrs. 6 mos.	Tonsils and pharynx.	..	"	.... ..	"	. ....	Died 6 days later.	Dr. Rottenburg.	
42	2 yrs. 9 mos.	Tonsils and nose.	..	"	7th day.	"	..	Died 2 days later of secondary croup.		
43	22 months.	Tonsils: membrane coughed up.	. .	"	6th day.	"	Recovery.	.....	Dr. Horn present.	
44	4 years.	Soft palate and tonsils.	. .	"	.....	"	"	.....	Dr. Horn present.	Referred to me for intubation by Dr. F. Nordeman.
45	3 years.	Tonsils and palate.	Pneumonia.	"	.....	"	.....	2 days later secondary croup and pneumonia.	Dr. Brothers present.	Referred to me by Dr. Lyttle.
46	11 months.	Membrane coughed up.	.. ..	"	. .....	"	.....	Pneumonia and secondary croup 2¾ days later.	Dr. H. G. Lyttle.	
47	4 yrs. 6 mos.	Pharynx, etc.	... . ..	"	.. ..	"	.....	Died 3 days later of secondary croup.		

RÉSUMÉ OF CASES.

Under three years of age.				Three years of age and over.			
Age.	No.	Recovery.	Death.	Age.	No.	Recovery.	Death.

Total.....	29	11	18	Total.....	18	9	9

Twenty-nine were under three years of age, 11 recoveries; 18 were three years old or over, 9 recoveries. Other points of interest will be developed later on.

4. When an intubation-tube is in position reflex spasm can no longer take place—the diseased structures are kept apart and *at rest*.

I do not forget that after a tracheotomy the membrane below the opening, even though recent, is apt to be expelled as soon as the trachea is opened or the tube inserted; that upon the vocal cords and in the larynx—and *here* is the point—is not thrown off for from six to sixteen days or more in a patient upon whom tracheotomy has been done. Though the greater amount of air enters the lung through the tracheal cannula, some air passes through the larynx and alongside the tracheotomy-tube; the laryngeal structures are more or less active, and are not as quiet as when separated by the intubation-tube.

5. Granulations are of frequent occurrence after tracheotomy, and require to be removed before the cannula can be dispensed with. They do not form after intubation; if ulceration be produced, the ulcers are superficial and soon heal.

As long as the respiration is obstructed and expectoration free, there is no occasion for the removal of the tube until five or six days have elapsed. If, during this period, the breathing becomes noisy and does not become quiet after the subsidence of a paroxysm of cough purposely induced by the ingestion of lime-water, etc., or if it be suspected that membrane be loose, and there is danger of obstruction, the tube ought to be taken out, to permit removal of the obstacle, and then reintroduced, if necessary.

I do not favor its frequent removal, nor is it necessary for the purpose of allowing the patient to take nourishment. It is safer and easier to insert the stomach-tube, through the mouth or nares, and thus nourish the child. We must not forget the danger of crowding membrane down in the reintroduction of tube.

When diphtheritic patches are visible upon the tonsils,

pharynx, or in the nose, I generally wait until they disappear before the intubation-tube is permanently removed. No membranes being present in the fauces, it is well to remove the tube at the end of five or six days; if the dyspnœa return, the tube can be reintroduced at once or after the lapse of a few hours. The hoarseness and aphonia which persist when tube is removed yield to general treatment in from one to three weeks.

The prognosis in intubation (and this applies to tracheotomy as well) is better when the evidences of general infection are mild or wanting; when the operation is done in cases in which the symptoms of asphyxia predominate, and the local lesion—the membranous deposits in the larynx—constitute the main danger to the patient. It is unfortunately true that in many instances it is not always possible, amid an aggregate of symptoms, often very complex, to distinguish perfectly the symptoms due to the local trouble in the larynx and those due to the sepsis or other complication. In view of the simplicity of the procedure and the comparative ease and rapidity with which it can be done, I have often intubated (the stenosis being sufficiently well marked to warrant it) regardless of the tender age and no matter how hopeless the cases from septic or other complication, the object being to allow the child to breathe more easily and to render its condition more comfortable, to prevent asphyxia with its struggles and suffering.

No positive prognosis can be given until forty-eight hours at least have elapsed. Though the dyspnœa be relieved, the membrane may extend downward, pneumonia set in, cardiac failure occur, systemic infection take place, and paralysis, nephritis, or heart-clot render the prognosis bad. If no marked elevation of temperature occurs and the respirations do not become accelerated during the first two or three days, the case will probably pursue a favorable course. Exceptionally a nephritis or late pneumonia will cause a fatal termination after the fifth or sixth day.

Intubation relieves the stenosis and keeps the larynx patent, so that air can gain free access to the lungs. It is thus a symptomatic expedient, so to say, resorted to, not with a view to cure the disease itself, but rather to overcome the obstruction to respiration. This should not be forgotten. We still have to deal with a serious disease and must meet other indications as they arise. What medicines are to be given? Dr. Northrup answers, "Milk and whiskey." He further adds: "I have occasionally found my tubes well corroded when enthusiasts in bichloride treatment and advocates of iron have been hard to manage." At the risk of corroding my tubes and being included among the "enthusiasts," I would state that I continue the use of the "bichloride" throughout the disease.[1]

If there be extensive diphtheria of the fauces, iron and chlorate of potash are indicated. If the nares be involved, nasal injections are resorted to. If other symptoms arise, the appropriate remedies are prescribed. In cases of threatened heart-failure, hypodermics of brandy, ether, camphor, caffein, etc., may be employed. High temperature is treated by antipyretics either by mouth or suppositories.

By means of Spencer's steam atomizer, steam is kept up continuously. Alcoholic and other stimulants are not to be neglected.

Alimentation is of primary importance in this as in any other severe affection. Disgust for every article of diet is a very unfavorable symptom. As a rule the little patients will not take food well from parents or friends, and whenever possible it is advisable to insist upon the presence of a good nurse. Even then personal supervision should be exercised, and precise directions left; too much latitude should not be given, or much left to the discretion of the attendant not familiar with the requirements of the case. The proper preparation of the food ought to be looked into by the physician. I have frequently been told that it was impossible to administer anything to the child. Sitting down by the bedside and personally attending to the feeding, I have been able to make the child take a reasonable amount of nourishment, either by threats of punishment, insertion of gag, force, or bribery. Trousseau very truly says: "There are no rigid rules in respect to the choice of food. We are often obliged, in some individuals, to satisfy the strangest possible caprices of taste." Some five years ago I performed a tracheotomy in a case of whooping-cough complicated with membranous laryngitis. Cyanosis was so far advanced that the operation was practically done without an anæsthetic. The boy, of Russian-Polish parentage, absolutely refused milk, stimulants, and usual articles of diet. Any attempt to force him would provoke him to such an extent that he would tear his hair, toss about wildly, and have a severe paroxysm of cough, often bringing up considerable quantities of blood. I was finally compelled to allow him to have his own way and to permit him to select his own dietary, his favorite dish being a compound composed of dried pears, carrots, potatoes, and meat stewed together. Of this he would eat two or three heaping soup-platefuls daily. The boy recovered. I mention this case, which is exceptional, merely to show that rigid rules cannot always be carried out, and in rare instances a departure from well-established precepts may not be attended by any untoward consequences. If after repeated attempts to give proper food I fail, I do not hesitate to allow the little fellow full latitude as regards his diet, provided rectal feeding be not possible and a resort to the use of the stomach tube (through nose or mouth) be attended by marked prostration.

For several hours after the tube has been introduced nothing should be allowed but small pieces of ice dipped in brandy or wine. These will be readily taken and will not induce coughing to any extent. At the next visit (three to four hours later) the physician should make it a rule to endeavor to discover how much fluid can safely be allowed at a time. Solids and semi-solids will be swallowed without much difficulty. Fluids, however, provoke considerable coughing. We must remember that the epiglottis is only an accessory to the closure of the larynx, and that the other more important factor, the action of its constrictor muscles, is prevented by the presence of the cannula; it is therefore evident that the deglutition of fluids can never be perfect with any form of tube in the glottis. If the head of the tube be too large, or ride too high in the larynx, the difficulty is greater.

It is my practice to sit by the bedside and endeavor to discover the idiosyncrasy of the little patient as regards the ability to swallow fluids. I begin with a teaspoonful of brandy and milk; if this be swallowed well, the nourishment is continued in teaspoonful doses, or larger amounts if well tolerated. If much cough follow, the quantity is diminished; in some instances but ten to twenty drops can be taken, and are then to be given by means of a medicine-dropper. This frequently happens in very young children, in such under eighteen months. In the case of older children we may allow them to sit up and take their food slowly from a cup or spoon—in fact, permit them to feed themselves as much as possible.

Medicines may be administered in the same manner. It is far preferable to gauge the patient's ability to swallow than to allow him to take indefinite amounts, which are coughed up as soon as taken, and only tend to add to the discouragement and torment of the little one.

[1] The deductions of Thallon (New York Medical Journal, April 12 and 19, 1884) prove not only that the bichloride is a proper antifermentative, but also that the doses must be larger than usually recommended. Following the teachings of Jacobi (The Medical Record, May, 1884), I have kept these patients under the influence of mercury. From one-sixth to one-half and even a grain (according to the urgency of the symptoms and age of child) may be given in divided doses in twenty-four hours, and continued for a number of days without producing any untoward results. The medicine is continued even after intubation; and when the difficulty in swallowing is great, tablet triturates of bichloride, one-fortieth of a grain, are powdered and mixed with a small amount of sugar and placed dry upon the tongue, ice being given at the same time to facilitate solution and prevent the drug reaching the stomach in too concentrated form.

Solids and semi-solids are better taken than liquid when there is pain and difficulty in deglutition, as they do not provoke coughing to the same extent. Thick soups, farinaceous food with milk, chocolate, cream, soft-boiled or scrambled eggs, frozen or condensed milk undiluted, may be allowed. Ice-cream, water-ice, and jellies of various kinds, with or without wine or brandy, may be tried. To children a year or so of age I have given rice, barley, or oatmeal water, cooked thick and strained, with white of egg and milk, a little salt and sugar being added to make it more palatable.

Rectal nutrient injections I have used in one or two cases; in only one case was I compelled to use the stomach-tube (Davidson syringe and Jacque's catheter).

Dr. Caillé and others, in order to lessen the dangers of pneumonia or pulmonary complications from the possible entrance of food into the trachea, advise rectal alimentation or feeding by the stomach-tube (THE MEDICAL RECORD, March 19, 1887).

This, in my opinion, is going too far. If the hints thrown out above are followed, I do not think that feeding by mouth will add materially to the danger of pneumonia in this class of cases. Furthermore, we must remember that pneumonia complicating diphtheritic laryngitis is a rather frequent occurrence and is usually a broncho-pneumonia and results from rarefaction of the air in the respiratory passages during the period of impeded respiration, with consequent collapse of pulmonary tissue and dilatation of blood-vessels, and hence a disturbance of the circulation. . . . Lobular pneumonia will result from the aspiration of pieces of membrane into the smallest bronchi. . . . Second form of pneumonia is from the beginning of a fibrinous character (Jacobi). The danger exists, I admit, but is greatly exaggerated, and I have not been able to find the records of a single case in which, at the autopsy, the pulmonary inflammation was found to be due to the aspiration of particles of food into the bronchi after intubation.

In the first few cases Dr. Denhard, misinterpreting the directions, inserted the tubes so that the bevel of the flange looked upward and forward, and in these instances the curious fact was observed that the patients could swallow very well. A number of gentlemen in Chicago have had a similar experience, and the reversed position is preferred by many, among them Professor Hoadley. The latter maintains that the flange of the tube, as placed by him deeply in the vestibule of the larynx, in no wise interferes with the functions of the epiglottis or the ary-epiglottic fold. Its removal, however, is attended with considerable difficulty. In order to test this further Dr. Denhard has lately introduced the tube in the reversed position and the patient was able to swallow with facility and comfort.

In this connection it may be well to refer to Dr. Waxham's modification of O'Dwyer's tubes, devised to overcome the difficulty of nourishing the patient. They are made with smaller heads and are provided with a rubber collar with an artificial epiglottis attached. The collar projects sufficiently to prevent the tube slipping into the trachea, and being more elastic, fits more perfectly into the larynx than the large metalic heads. When the child swallows, the epiglottis presses the artificial epiglottis down, so as to completely cover the aperture of the tube. As deglutition ceases the larynx falls and the elasticity of the rubber throws the artificial epiglottis upward. Even with this addition the deglutition of liquids is not perfect; some enters the larynx.

The pertinent question has been asked, Does intubation leave the patient without any of the advantages offered by tracheotomy?

In my experience and that of others who have given the new plan a faithful trial, intubation secures to the patient every advantage afforded by incision of the trachea. The insertion of an O'Dwyer's tube relieves the stenosis as promptly, thoroughly, and efficiently as tracheotomy. Expectoration is more readily accomplished after intubation, for the ability to close the glottis is preserved, the cough consequently is explosive and full, and the mucus and shreds of membrane are readily brought up.

Furthermore, intubation will save many lives in cases in which tracheotomy would not be permitted; it will save many a patient from the need of tracheotomy; and "finally, it will save many that could not be saved by tracheotomy." The last applies particularly to children under three years of age. Fifty-two of Waxham's cases (up to December 14, 1886) were three years or under, a great many nursing infants, with 13 recoveries (twenty-five per cent.). Among the recoveries were 1 nine months old, others respectively, fourteen months, eighteen months, and twenty-two months of age (*Med. News*, January 1, 1887).

My own cases comprise 29 under three years of age with 11 recoveries, including one nine and one-half months old, one ten and one-half months, two eleven months, and one one year old.

I have endeavored, to the best of my ability, to bring before you a faithful view of the subject under consideration, to give the dark as well as the light sides, to present the advantages as well as the imperfections of the measure. The picture may be rose-colored, but my experience warrants the favorable and even enthusiastic view I have taken. I have seen child after child die of laryngeal obstruction in instances where tracheotomy was objected to, and of twelve cases in which I have operated, ten have died. I have furthermore assisted at the operation and more or less closely followed the after treatment of at least a score of cases in the practice of various friends. The results have not been brilliant or encouraging. It is thus evident that I do not reject the cutting operation upon theoretical grounds or insufficient experience. I appreciate the relief afforded by tracheotomy and have urged its performance in spite of discouraging results. Intubation affords relief as effectually and as thoroughly as tracheotomy. Moreover, it is a simpler and safer method. "The child is swathed, the gag is in, the tube is in, the thread is out, the gag is out, and the relieved and bewildered child is looking about, coughing, quite unable to comprehend the surroundings." Those who have witnessed the operation of intubation recognize the truth of the above and appreciate the benefits and advantages as well as the simplicity of the procedure. Many authorities, without any familiarity with the measure and without a proper study of the subject, condemn the plan and attempt to discredit the assertions of its advocates. The objections are theoretical.

Edmund Owens ("Year-Book of Treatment for 1886," page 164) concedes that he "neither has nor desires a practical acquaintance with it," and yet condemns the method. Michael, of Hamburg, says the method is as dangerous as it is impracticable. Thus far it has not met with much favor in England or on the continent.

In concluding, it is but just that we acknowledge the debt of gratitude we owe to our *confrère*, Dr. James O'Dwyer, considered by Jacobi the most deserving and most modest of all men. The patient, painstaking, and unostentatious manner in which he has conducted his experiments and investigations deserve due recognition at our hands. The perseverance, ingenuity, and originality shown in perfecting the method merit our admiration. The disinterestedness, candor, and modesty, so characteristic of the man, and which stamp his references to this invaluable addition to our resources in the treatment of croup, cannot be extolled too highly, and deserve more than mere praise or words of fulsome flattery. Finally, I heartily indorse the sentiment expressed by Dr. Ingals and join "in acknowledging the nobleness of the profession at large which tolerates no secret method, but generously donates to mankind every improvement in the healing art." Among the latest, but not the least, may be classed intubation, rightly considered as "one of the great advances in this age of medical discoveries."

FEEDING AFTER INTUBATION OF THE LARYNX.

With Exhibition of Tubes Modified to Overcome Difficulty in Feeding.

By JOSEPH O'DWYER, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK FOUNDLING ASYLUM.

From the very beginning of my experience with intubation I recognized the fact that the greatest objection to this operation, and the one most difficult to overcome, was that of feeding the child while the tube remained in the larynx. I therefore began very early to try various modifications in the size and shape of the heads of the tubes with a view to remedying this defect. I will show you a few of these modifications in the order in which they were made.

1. I first had the tube made with a very small shoulder, which rested on the vocal cords, while the lateral portions of the flange occupied the ventricles, thus permitting some action of the constrictors, such as occurs under normal conditions, to aid the epiglottis in protecting the larynx during the act of deglutition. The objection I found to these small-headed tubes was the tendency of the swollen tissues to close over the aperture above, and there was also the danger that the tube might be pushed through into the trachea during attempts at extraction.

2. My next modification consisted in gradually increasing the size of the head and giving the upper portion of the tube a backward curve in order to carry it away from the base of the epiglottis, at which point the straight one frequently produced ulceration.

3. The posterior portion of the tube was made longer than the anterior, or oblique from before backward and upward, in order to allow the epiglottis to come in contact with it sooner and with greater force when pressed down by the base of the tongue.

4. The next modification was to increase the size of the head so as to make it fill the cavity of the larynx and thus prevent the entrance of fluids around it, for cough will be excited by contact of a foreign body with any portion of the mucous membrane of the glottis. The heads of the tubes now made are much larger than is necessary, but as deglutition, if no better, is certainly no worse, I have not changed them for the reason that the large head renders the extraction less difficult.

5. The head of the tube was now made concave on its upper surface. This shape was suggested by taking a wax cast of the larynx and pressing the epiglottis over it while the wax was still soft. The impression made on the wax was similar in shape to that which you see in this tube. I have used this modification in a few cases, but without witnessing any apparent improvement in deglutition. Should it not prove otherwise objectionable on a more extended trial, this form of head may be an advantage, as it would render the removal of the tube, which is now the more difficult operation, much easier than its introduction, for the extraction, striking anywhere on the concave surface, would naturally and easily glide into the aperture.

6. In some cases a double backward curve has been given to the upper portion of the tube, the first curve being covered by the flange and the second being a little lower down. This has been used in several cases, but I have not seen any improvement in deglutition to result therefrom.

This shape is advantageous, however, in one respect. Autopsies were made in three cases in which these modified tubes were used, and not the least abrasion was found on the anterior wall of the trachea, at the point corresponding to the lower extremity of the tube, where more or less ulceration is not uncommonly produced by the tubes ordinarily used. This ulceration is sometimes quite marked in cases in which the vital powers have been much reduced by a previous attack of scarlet fever or measles or both, and is produced in the following manner: A tube in the larynx acts as a lever, with the posterior commissure as a fulcrum. During every act of deglutition the epiglottis presses the upper short arm of the lever backward and tilts the lower long arm forward against the wall of the trachea. First, the pseudo membrane disappears for about one fourth of an inch above and below the end of the tube. I have seen many cases in which this alone occurred, and others in which the lesion varied from simple loss of the epithelium to pretty extensive ulceration. Several years ago, when I was using short tubes, from one to one and one-half inch in length, and of larger calibre, I never found ulceration in the trachea, but this lesion was present in almost every case just below the vocal cords in the subglottic division ot the larynx.

I also show you one of Dr. Waxham's modified tubes with rubber epiglottis, which I have not yet tried.

With all these modifications, and others that I have not mentioned, I have found about the same difficulty in the swallowing of fluids, some of which, when compressed by the muscles of deglutition, will be forced under the epiglottis, no matter how accurately it covers the aperture of the tube.

There are still other modifications that I intend to try, and as other men are working in the same line, there is reason to hope that some device will yet be found to overcome this difficulty.

Solids and semi solids, when there is an appetite for such food, and when the patients can be induced to take it, are swallowed much better than fluids and do not enter the tube, as far as I am aware. Indeed, there is no reason why they should do so, for a bolus of food as it passes downward tends rather to press the epiglottis more firmly over the mouth of the tube than to raise it, as happens in the case of fluids. I make an exception to this statement in the case of malignant diphtheria of the larynx, a few cases of which I have operated upon, in which the epiglottis is converted into a mass of an almost globular shape by reason of the infiltration into its tissues, whereby its normal functions are completely abolished.

Some children swallow remarkably well after intubation, others very imperfectly, while a few refuse absolutely to swallow anything. This difference is to be explained partly by the condition of the epiglottis, whether very much swollen or not, and partly by the absence or presence of a desire for food. I have often known children to refuse milk or any other kind of nourishment, when they would drink water, beer, or anything that they liked, with very little difficulty. On several occasions I have removed the tube for the purpose of giving nourishment, but found that the patients could not be induced to take food any better than before. This occurs more frequently in cases of severe complicating nephritis which occasions nausea and a loathing of food.

There is sometimes an apparent improvement in swallowing after intubation, and more nourishment is taken than before the operation. This is due to the relief of the dyspnœa, which, before the insertion of the tube, was so urgent that the little sufferer could not afford the loss of the one or two respirations that would be necessitated by making a single act of deglutition. As a rule, the longer the tube remains in the larynx the better the patient learns how to swallow. I have observed this in adults as well as in children. One woman declared after intubation that she could not swallow anything in either solid or liquid form, and it was necessary to feed her by the stomach-tube. After the laryngeal tube had been retained for two or three weeks she took as much food as the stomach would tolerate and, in addition, large doses of iodide of potassium.

Exceptions to this rule are found in those cases in which, before intubation, nourishment was refused because of the painful condition of the pharynx, or because

of anorexia induced by nephritis, and in others in which a great deal of pain and irritation, caused by ulceration on the anterior wall of the trachea, previously alluded to, are present.

I always instruct children who are old enough to understand, to drink as rapidly as they can and then cough to expel any fluid that may have entered the tube, instead of coughing after each deglutition as they usually do. In quite a number of cases I have been obliged to supplement feeding by the mouth by rectal alimentation, with or without stimulants, as indicated. In only a few have I had to resort to the stomach-tube.

Intimately connected with the question of feeding after intubation is that of food-pneumonia, so much talked about of late. I will first refer briefly to the most important factors concerned in the causation of pneumonia as a complication of croup, and will then give some reasons for believing that food is not one of them. The several etiological factors may be grouped as follows:

1. The presence of secretion in the lower air-passages, in consequence of the frequent association of bronchial catarrh and croup.

2. The excessive amount of blood drawn to the lungs when there is sufficient obstruction in the larynx to prevent the free ingress of air required to fill the vacuum produced by the inspiratory expansion of the chest.

3. Atelectasis from the same cause or from plugging of some of the bronchi by pseudo-membrane.

4. The presence of a tube, whether it be in the larynx or in the trachea, not because it may admit a little of the milk or other fluids swallowed, but because it prevents closure of the glottis, and consequently prevents that compression of the air which is essential in order to give full expulsive power to the cough. The irritating secretions, therefore, instead of being promptly expectorated, accumulate, and are aspirated into the air-cells, where they sooner or later excite inflammatory changes.

When we consider the nature of these influences, some of which are constantly present in severe cases, it ought not to be surprising to find pneumonia, especially of the lobular form, a rather frequent complication of croup. And this is particularly so after operation, whether by tracheotomy or intubation.

As opposed to the food-pneumonia theory, I offer the following:

1. I do not believe, and there is no evidence, so far, to prove, that any of the fluid entering the tube ever reaches the bronchi, for it is promptly expelled by coughing.

2. Those cases in which the croupous process does not invade the bronchi, and in which there is little or no bronchial catarrh, no matter how imperfectly they swallow, rarely, if ever, develop pneumonia.

3. Intubation in chronic stenosis of the larynx, in the adult, is not followed by any inflammatory changes in the lungs. In one case of this kind I have already introduced a tube over fifty times, leaving it in the larynx on several occasions as long as a week at a time. This patient, owing partly to a deformity of the epiglottis, swallowed both solids and liquids very imperfectly, but never developed even the slightest amount of bronchitis. Another female patient, who had worn a tracheal cannula for over two years and who was in failing health and suffering from bronchitis at the time that she was intubated, rapidly improved after the tube was inserted into her larynx, and the external wound was closed. The bronchitis also disappeared within a reasonable time. This patient wore the tube in her larynx continuouslyfor over ten months, and enjoyed excellent health during the entire time.

There is no objection to the use of emetics, if indicated, after intubation, and there is no danger that the vomited matters will enter the tube, as no resistance is offered to their escape from the œsophagus, such as must be overcome when food or drink enters this canal from the pharynx

Finally, I wish to show you two hard-rubber tubes which are suitable for use in any form of acute stenosis of the larynx in the adult. The larger is intended for a large adult male, the smaller for a small-sized or young adult male, or for a female. Whether they will be any improvement on the metal tubes that I have been using remains to be settled by a more extended trial. I have used the smaller of these in two women, who had previously worn metal tubes of a much smaller calibre. One of the patients expressed a decided preference for the heavy tube, which, she said, sank deeper in the larynx and enabled her to swallow more easily than did the light-rubber tube. But although one weighed one ounce and three-quarters and the other only one hundred grains, she could not appreciate any difference in the weight as it was in position in the larynx. The other patient, while she could not swallow as well with it, was equally strong in her preference for the lighter tube, saying that it gave her less pain and irritation, and enabled her to expectorate more easily. These tubes are made by Tiemann & Co.

PATHOLOGICAL ANATOMY OF THE RESPIRATORY TRACT AFTER DEATH FROM LARYNGEAL DIPHTHERIA AND INTUBATION.[1]

By W. P. NORTHRUP, M.D.,

PATHOLOGIST TO THE NEW YORK FOUNDLING ASYLUM.

In my paper read before this Academy in December last (see MEDICAL RECORD of December 11, 1886), entitled "Laryngeal Diphtheria, Intubation, and Pathological Anatomy," etc., I analyzed the cases found in the post-mortem records of the New York Foundling Asylum. There were at that time 87 cases recorded of death from laryngeal diphtheria.

Of these, 50 were males, 37 females. Average age was two years and seven months. Number of children dying under one year, 13; between one and two was 9; two and three, 10; three and four, 36; four and five, 11; five and six, 1; six and seven, 1; unknown, 6—total, 87 cases.

"The greatest mortality, as we see, was from three to four years of age, where we find 36 of the 87 cases. The next number falls abruptly to 13, representing those dying under one year."

In 56 the diphtheria began in the larynx. Of the 87 cases 22 followed measles, 8 followed scarlet fever. In 54 cases there was pneumonia, the diagnosis of which was made either from obvious signs of consolidation, or, where this was not well developed, from the microscopic findings. Not in all cases did there seem to be enough pneumonia to be the cause of death. In 29 cases there was estimated to be enough. In 27 cases bronchial diphtheria was the prominent lesion. I will here repeat that I do not rule out pneumonia, because lung inflates easily by artificial means and returns nearly to its normal color. I am not willing to admit that it is collapse, and not pneumonia, on that test. In cases of doubt the microscope has been used to determine the nature and extent of the lesion, and in the records referred to the diagnosis heading the history and post-mortem records has been made on the anatomical basis.

Since January 1, 1887, there have been added to these records 20 cases, making in all 107. These will be interesting and instructive, because they are all cases of laryngeal diphtheria occurring in a fatal epidemic of measles. Of the 20 cases all had measles and pneumonia; 8 had scarlet fever with measles; and 13 had, in addition, well-marked nephritis. These points are mentioned to show the severity of the epidemic, which in four months has added 20 cases to the former record.

I said in my paper that I had never found any ulcers of the trachea which were more than a rubbing away of

[1] Read before the New York Academy of Medicine, June 2, 1887.

the epithelium. I have this evening to show you the lesions of a severe epidemic, in which the patients have been overwhelmed with scarlet fever and measles and pneumonia and nephritis and diphtheria. On these glass slides are shown the ulcers in gross, from four tracheas, which ulcers, you will see, extend in depth to the rings of the trachea, laying them bare. The lower end of the tube, at each movement of swallowing, rubs against the anterior wall of the trachea. In this severely fatal epidemic we find what we did not in previous cases, viz., deep ulcers. Of the 20 cases 5 had tracheal ulcers deep enough to be of serious moment. I have never seen ulcers made by the head of the tube worthy of consideration. It amounts simply to necrosis of the epithelium, and will heal without contraction.

One of the first questions to be asked is whether or not milk, which occasions cough, passes into the finer bronchi and alveoli and causes pneumonia—foreign-body pneumonia, aspiration pneumonia, *schluck pneumonie*. I may answer, briefly, I have never found any evidence that it did find its way into the finer bronchi. I am familiar, too, with the article of Orth, of Göttingen, recently published, and I find nothing corresponding to his description.

I am endeavoring by experiment to determine how far the fluid passes downward into the air-passages. Fluid bathing simply the under surface of the epiglottis may cause violent cough. The experiments are in this line. By some means register the depth to which the fluid descends, either by harmless staining-fluids or by finely divided carbon suspended in milk. Thus far I have no results to publish.

This paper has but two points to add to that of December on this particular feature of the discussion.

First, after all that has been suggested on the subject, I find no evidence that milk, or food of any kind, has passed into the finer bronchi and alveoli of patients wearing the laryngeal tube.

Second, that in patients the subjects of previous exhausting disease the lower end of the tube may cause ulceration, even when worn the usual number of days. This ulceration may easily amount to a complication.

CONTRIBUTION TO THE DISCUSSION ON INTUBATION OF THE LARYNX.[1]

By A. CAILLÉ, M.D.,

NEW YORK.

I WISH to state at the onset that we cannot this evening speak a final word as to the actual merits of intubation.

It is true that a large number of cases are on record, but it is equally true that many of these cases are reported in a superficial manner, and therefore lose their value as statistical material.

I must confess that Dr. Huber and Dr. Brown have presented their cases in a manner calculated to inspire confidence in the conclusions which they formulated.

I believe, moreover, that it is a good plan for those who have had experience with both tracheotomy and intubation to come together occasionally and compare notes; and taking this view, I will briefly state my own experience.

I have done tracheotomy 21 times, with 5 recoveries. I have intubated 16 times, with 6 recoveries. Of the intubated cases 9 were cases of nasal or pharyngeal diphtheria and laryngeal stenosis, with 2 recoveries; 6 were cases of true membranous laryngitis, and no visible diphtheritic exudate on fauces, with 3 recoveries; 1 case was probably a severe simple inflammatory stenosis of five days' standing, which had not improved under ordinary treatment, with very urgent dyspnœa, 1 recovery.

Most of these cases were seen in consultation, and intubation was done rather late, and I am convinced that without active interference every one of these children, whose ages ranged from one to seven years, would have died of suffocation.

I believe that I would be able to report at least one more recovery if intubation had been done earlier in one case, for breathing had actually ceased and artificial respiration had to be practised.

My best results in intubation were obtained in cases of undoubted membranous laryngitis, in which diphtheria of fauces was not visible at the time of intubation.

Now this is quite the reverse of my experience with tracheotomy, for most of the children operated upon for true membranous laryngitis died from an extension of the membrane into the finer bronchi, and it made apparently no difference whether the trachea was incised above or below the thyroid gland. The cause of death in such patients as did not recover after intubation was, in the majority of cases, catarrhal pneumonia. In most of the fatal cases I gave some liquid nourishment, which may have provoked pulmonary inflammation through being aspirated. Of late, I have given only solids, chopped very fine and moistened, and small pieces of ice to quench thirst; since that time my results are much better.

One case deserves special attention. I intubated a child, one year old, with extreme stenosis but no visible diphtheria. I removed the tube every other day to feed the child, as it could not swallow, but I was obliged to reintroduce it. On the twelfth day I noticed pharyngeal and nasal diphtheria, and on the fourteenth day, the child died of exhaustion, with the tube *in situ* and the lungs free. If I were asked to express my personal opinion as to the value of intubation, I would say:

1. In *general practice* intubation is preferable to tracheotomy in urgent laryngeal stenosis of children in the majority of cases.

2. When pharyngeal or nasal diphtheria and laryngeal stenosis are present at the same time, intubation should be practised in preference to tracheotomy, when the surrounding circumstances are such as to preclude the possibility of proper and intelligent after-treatment.

3. Tracheotomy is preferable to intubation in such cases of larnygeal stenosis, with pharyngeal or nasal diphtheria, which appear from experience *hopeless*, without *sufficient stimulation and nourishment* and proper local treatment of naso-pharynx, *provided the operation and after-treatment can be conducted under the most favorable surroundings*.

4. These conclusions pertain to intubation with the present style of tube.

[1] Read before the New York Academy of Medicine, June 2, 1887.

COLDS TAKEN IN THE CARS.—In these days when travel by railroad is very common, a few words to the patients on the best means to prevent taking colds in the cars will be useful. For men, a light cap, one that will cover over the ears, so as to serve as a night cap, will be desirable. In cold weather a woollen cap is best. This cap should be put on as soon as the car is entered. A loose blouse should take the place of the coat usually worn. Slippers must not be worn. If there is a draught in the car, face it, do not let it strike the back. Have the bed made with its head toward the engine; the dust will then be driven to the foot, where it will do the least harm. But be sure to have a sufficient quantity of bedclothes to keep warm. A soft, loose-knit, woollen hood is the best head-wear for women; this should be worn at night also. It should be warmer in winter than in summer months. The corsets should be removed at night, and a loose woollen wrapper worn for a night-dress. The stocking supporters as well as every constricting band around the waist should be loosened. Every adult should take from five to ten grains of quinine on going to bed. It will be well to rub the hands, feet, face, and neck with a little vaseline at the same time.—*Journal of Reconstructives*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 18, 1887.

THE TREATMENT OF WOUNDS OF THE INTESTINES.

ALTHOUGH American surgeons may have little to learn from abroad concerning the treatment of abdominal wounds involving the intestines, it may not be uninteresting to hear what others have to say concerning it, especially when they are surgeons of acknowledged authority.

At the annual conversazione of the London Medical Society, held on May 2d, Sir William MacCormac delivered the address, taking for his subject "Abdominal Section for the Treatment of Intraperitoneal Injury." Confining his attention almost entirely to wounds of the bowel, the speaker remarked that the diagnosis was of primary importance, as upon its speedy determination must depend the success of our treatment. If we wait till the diagnosis has been established by the occurrence of peritonitis, the services of the surgeon are no longer called for. To clear up the diagnosis he recommended that the wound should be thoroughly examined, precautions being taken to exclude septic influences. If probing fail to clearly establish the fact, or otherwise, of penetration, the wound should be enlarged and explored to its termination, either in the parietes or more deeply. Enterorrhaphy was at the present time admittedly the best treatment for all punctured and incised wounds attended by protrusion, unless the parts were so damaged that an artificial anus seemed preferable. In cases of stabs and gunshot wounds unattended by protrusion, the common practice, heretofore, had been to give opium and enjoin rest, in the hope that adhesions might form. In the vast majority of instances such hopes were illusory. Another practice commonly recommended was the formation of an artificial anus by attaching the margins of the wound in the gut to the skin, but where it was possible to avoid it this course was highly undesirable, and it was certainly unnecessary in those cases in which the injury did not extend more than half-way round the gut, or when it was on the convexity of the bowel.

"In cases of injury," remarked the speaker, "we but half accomplish our work if we do not at once attempt to restore the continuity of the intestine."

Three conditions were enumerated as being required to insure successful suture of the intestine, viz. (1), two sufficiently broad and wide surfaces of peritoneum must be brought into contact; (2) the mucous membrane must be excluded, for when the needle passed through the whole thickness of the gut peritonitis generally ensued from leakage taking place along the line of the thread; (3) rapidity of execution was of extreme importance, and that form of suture was the best which could be effectively employed in the shortest time. Sir William preferred Lembert's method of suture for all wounds of the bowel. Sufficient inversion could be easily accomplished without causing obstruction of the lumen of the tube. To cleanse the abdominal cavity from all blood and foreign matter, the best and gentlest method was, he thought, to employ irrigation with a three-per-cent. solution of boracic acid at a temperature of 100° F., made with water previously boiled. The external wound was to be closed, as after ovariotomy. If the operation were done shortly after the accident, drainage might be dispensed with, but if some time had elapsed, or peritoneal inflammation were present, it would be best to drain.

INSTINCT IN MEDICINE.

A RECENT French writer, M. Delaunay, has discoursed upon the instinct of animals with reference to the care which they take of themselves in emergencies arising from physical injuries. He adduces many interesting facts, some of which are familiar, while others are new and exceedingly novel. For instance, he notes that dogs suffering from gastro-enteric troubles, due to improper food, eat certain grasses which have a purgative effect, and thus rid themselves of the offending material. Still more striking is the habit among ants when any of their antennæ become broken off. The comrades of the injured animal gather about it, and from their own bodies secrete in some sort of way a soft, gelatinous material which they plaster upon the injured member, and under this protective dressing the missing part is redeveloped from the remaining stump.

M. Delaunay recites many interesting facts of this nature. Some of them are his own observations, others are those of Sir John Lubbock, the distinguished entomologist, and of other scientists. From this premise he branches out on to the topic as to how far natural instincts in man may be trusted to guide us in our therapeutic applications. He is inclined to think that they ought to be trusted much more than they are.

At the outset comes the pertinent fact that civilization, with its attendant prosperity, often perverts the natural instincts. Among the well-to-do classes luxurious habits are developed which affect the system contrary to the course of nature. We may grant that natural appetites are right to start with, but false views of physical life beget unnatural desires and cravings, to follow which is physical shipwreck. A person lives years in the country eating plain food and keeping good hours. He removes to the city, and shortly falls into the latter's pernicious habits of eating highly seasoned viands and turning night into day. The first milestone on this new road reads "dyspepsia." When the question of therapeutics comes up, the appetite, now perverted, though practically the instinct for the time being, is an unsafe guide; the patient's cravings for various articles of diet cannot be indulged.

Some authorities, however, give contrary advice. The late Austin Flint caused much comment at one time

when he read a paper on diet in dyspepsia where he virtually took the ground that the patient should be allowed to eat anything he wanted. Experience does not seem to stamp approval upon this recommendation.

True instinct with reference to physical actions is always in accordance with what is physiologically right. Whenever the system of a patient seems to have wandered from this path it is the province of rational therapeutics to return it thither. It does not do to tell a patient not to worry about his food, and to eat anything he likes. Such articles of diet must be recommended as will be acted upon by perverted secretions, and then gradually the organs of digestion can be brought up to their natural tone. Then proper juices will be elaborated, and a more liberal dietary can be entered upon.

THE AIR OF DWELLING-HOUSES.

English journals are wisely calling attention to an important paper recently published in the "Philosophical Transactions," by Professor Carnelly, Mr. Haldane, and Dr. Anderson, of Dundee. These gentlemen have analyzed the air of dwellings, and also the outside air, for carbonic-acid gas, organic matter, and micro-organisms. Statistics are given showing the comparative amount of these impurities in one-roomed houses and in houses with four rooms and upward. These figures indicate, also, as might be expected, an increase of disease in direct proportion to the crowding. The death-rate from phthisis, to be sure, is lower in those living in one- and two-roomed houses than in those living in three rooms, but this anomaly is explained when the early mortality of the former from other diseases is considered. Thus the death-rate per 10,000 from (1) diarrhœa, acute bronchitis, broncho-pneumonia, and meningitis is—for dwellers in four rooms and upward 19.6, for those in three rooms 27.6, for those in two rooms 39.7, and those in one room 59.8; from (2) phthisis the rates are respectively 13, 27.6, 24.4, and 14.6. The inquiry also showed the effect of impure air in promoting pulmonary disease; and as regards infectious disease the mortality from measles and whooping-cough seemed distinctly connected with the class of house, while, contrary to expectation, no such relation held for diphtheria.

THE DIAGNOSIS OF THE CROWN PRINCE'S MALADY.

Dr. Morell Mackenzie, of London, has sent a cablegram to The Medical Record in which it is stated that the tumor in the throat of the Crown Prince of Germany is of a dense warty character (Pachydermia Verrucosa).

A most important statement, based upon the authority of Professor Virchow, is that no morbid products are discoverable by the microscope in the submucous tissues. The prognosis, therefore, based upon this examination, is to be regarded as most favorable.

A growth presenting such characteristics possesses no elements of malignancy, and depending as it may upon various constitutional as well as local causes, is, as a rule, perfectly amenable to treatment.

This information thus received from most authentic sources would seem to set at rest the question of doubtful diagnosis and relieve the minds of the many interested in the nature of the Crown Prince's malady.

ILLEGITIMACY IN EUROPE.

Dr. H. Holland, of Westfield, Mass., has sent to us a sheet of medical statistics which has a somewhat depressingly numerical look, but which contains many facts of interest to the student of medical and social science.

In particular the statements made regarding the great and increasing number of illegitimate births in Europe are most striking and significant. To Americans, who have a high respect for the marriage relation, and who have been taught that in the stability of the family lies the strength of the nation, the fact that in Austria over one-half the births are illegitimate seems most astounding. In Vienna, according to L. A. Bertillon, among 1,000 births 509 are illegitimate: at Prague, 505. In Styria, Carinthia, and Olmutz the ratio is from 646 to 702 illegitimates out of 1,000 births! Austrian influence seems particularly inimical to legal paternity. This high rate of illegitimacy seems to prevail quite constantly throughout Germany, ranging from 1 illegitimate to 0 9 legitimates (Vienna, 1862), to 1 to 5.

The proportion of illegitimates is very high in Paris (1 to 3), but less in all France (1 to 12), and less in Great Britain (1 to 15), Spain (1 to 18.4), the Netherlands (1 to 23), Italy (1 to 27.8), and Greece (1 to 78.6). The low rates in some countries are due to the population being more largely rural. According to Bertillon, the great co-efficient of illegitimacy (in Austria) is Roman Catholicism. During ten years Austria had nearly a million of illegitimate births.

The point of medical interest lies in the fact that the illegitimates are almost always the greatest victims of disease. It is these that fill our asylums and hospitals. In every respect they constitute an inferior order of race. Conceived, often, during a debauch or in moments of intoxication, brought up in neglect, poverty, and misery, they furnish the largest part, proportionally, of the social burden which the healthy and strong have to bear.

According to Bouchut, the mortality among foundlings in Paris is fifty-five per cent. in the first year of life, and sixty-three per cent. in the second year of life. Such a rate is greater far than exists in many other cities, but it indicates, in general, the excessive amount of disease among this unfortunate class.

Dr. Holland finally quotes Legoyt as stating that the fact is established that the number of illegitimate births is increasing in Europe.

BRASS-WORKERS' DISEASE.

Very little attention has been paid in this country to a certain class of disorders observed among brass-workers. The best known class of symptoms is that constituting what is called "brass-workers' ague." After being exposed to the fumes of the molten metals, copper and zinc, the workman feels a sensation of discomfort and weakness, followed by muscular pains and then by a distinct chill, with headache, and often cough. After fifteen or twenty minutes a profuse perspiration breaks out; then in a few hours the improvement begins. The patient recovers in one or two days, but is liable to a relapse. Brass-founders' ague was first observed by Blaudet in 1845. It was described by Greenhow, of Birmingham,

in 1858, and again by Hirt. Brass is an alloy of copper and zinc, the latter being in the proportion of 28 to 32 per cent. In the process of making, the zinc deflagrates and fills the air with the powdered oxide. Dr. Greenhow believed, therefore, that brass-workers' ague was an acute poisoning with zinc. Hirt, however, thought it due to the mingled fumes of copper and zinc, because it is not observed among zinc-smelters. Recently Mr. Edgar Hogben (*Birmingham Medical Review*) reports a number of observations, and states his belief that brass-workers' disease is due to chronic or acute copper poisoning. Almost all patients who are copper- or brass-workers have a distinct green hue or band on the neck of the teeth between the crown and the gum. The edge of the gum is slightly blackened. The copious perspirations of brass-workers are often stained green, and white-haired workmen often have a greenish tinge to their locks.

These signs point to an absorption of copper by the workmen and favor the view that the "ague" is due, in large part at least, to this metal.

But these workmen also suffer from other symptoms of a chronic character, such as dyspepsia, metallic taste, colic, constipation and diarrhoea, nervousness, and pains of various kinds are felt. Deafness is not infrequent; cough and aphonia often occur. Paresis of the legs and symptoms like those of locomotor ataxia have been observed, and it seems probable that the copper can cause myelitis and neuritis, in the same way as does lead and other toxic agents.

News of the Week.

The Ohio State Medical Society met this week at Cincinnati.

Disabled Great Men.—The Emperor William is suffering from advanced senility, the Crown Prince from a laryngeal papilloma, and Bismarck from rheumatism; Mr. Gladstone has catarrhal troubles of his respiratory organs; Sir Michael Hicks-Beach has cataracts; Mr. Parnell has some unknown malady which makes him an invalid; Lord Randolph Churchill married an American lady and has the American disease, neurasthenia; Mr. Blaine is reported to be a *brightique;* Mr. Manning is hemiplegic; President Cleveland is rheumatic and lipomatosic; the Emperor of Russia is suffering from mental depression; Mr. Jacob Sharp is reported to be diabetic; while Father McGlynn and Mr. Editor O'Brien are not so well as they should be.

Suit against the New York Hospital.—A suit was recently brought against the New York Hospital by a patient who had been operated upon for cystitis by cystotomy. The damages claimed were $30,000, on account of impotence from injury of both ejaculatory ducts and wound of rectum. The left lateral incision was made. The plaintiff claimed that in consequence of the injury all his semen escaped into the bladder. It was shown by the testimony of Dr. W. T. Bull, the operator, and Drs. George F. Shrady and L. B. Bangs, that such an injury was impossible under the circumstances, and a verdict for the hospital was rendered accordingly.

A Proposed New Building for the Academy of Medicine.—Active measures are now being instituted toward the erection of a new building for the Academy of Medicine. There is certainly an urgent need for it. The present academy building is altogether too small. It is said that a site has already been selected in a desirable locality, between Sixth and Seventh Avenues, in Fifty-seventh Street. There are nearly enough funds to erect a suitable edifice, and members of the Academy and their friends are asked to contribute. The means toward the end should not longer be deferred. We should have a building worthy of the Academy. The Building Committee is commendably in earnest in the matter.

Practitioners' Society of New York.—Dr. George F. Shrady has been re-elected president of this Society for the ensuing year, and Dr. C. L. Dana, secretary.

The Country Practitioner's Advice to the City Physician.—Dr. E. P. Cook, of Mendota, at the last meeting of the Illinois State Medical Society, said with truth that the country practitioner could give the city physician good advice on many topics: First, not to allow the creation of any more medical colleges. Second, to limit the number of specialties. Third, not to make physicians out of persons in any way defective either as to morals, capacity, or preliminary education.

Appropriations for the Medical Congress.—The Illinois State Medical Society appropriated $750; the Nebraska Society, $50.

Medicine in Indiana.—At the last meeting of the State Medical Society, the President, Dr. G. W. H. Kemper, said that Indiana has now 1 physician to every 396 inhabitants—a ratio that is exceeded by only three States: Maryland, 1 to 329; Colorado, 1 to 341; and Oregon, 1 to 353. He suggested that unless Indiana is protected by some legal restrictions, she will eventually become a retreat for reckless and incompetent practitioners. One of the dangers the profession has to fear is the tendency to litigation by patients and friends for alleged malpractice in surgery.

The New Hampshire State Medical Society meets at Concord on June 21st.

The New Jersey State Medical Society meets at Beach Haven on June 21st.

Bellevue Hospital, New York.—Dr. George B. Fowler has been appointed Visiting Physician to Bellevue Hospital, vice Dr. E. Darwin Hudson, deceased.

Baltimore Academy of Medicine.—At the last meeting of the Baltimore Academy of Medicine the following officers were elected for 1887–1888: President, W. C. Van Bibber, M.D.; Vice-President, B. B. Browne, M.D.; Treasurer, G. Lane Taneyhill, M.D.; Secretary, C. C. Bombaugh, M.D.; Reporting Secretary, Wm. B. Canfield, M.D.; Executive Committee, T. A. Ashby, M.D., Robert T. Wilson, M.D., Hiram Woods, M.D.

Home for Incurables, Fordham, N. Y.—The Twenty-first Annual Meeting of the Society of the Home for Incurables was held at the institution on Saturday, June 11th, at 3 P.M. Several addresses were made to a large gathering of friends, who were gratified at the flourishing condition of the institution.

Colonial and International Congress on Inebriety will be held at Westminster Town Hall, London, S. W., Wednesday, July 6, 1887. A large attendance is expected.

German Hospital, New York.—Drs. A. Caillé and William Balser have been appointed visiting physicians to the German Hospital.

Dr. Charles E. Sajous, of Philadelphia, in correcting some remarks before the American Laryngological Congress, writes: "I am reported as saying that I 'believed that superficial organic alteration was of only temporary benefit.' Used singly this phrase implies one meaning, but coupled with the rest of my remarks the sense is entirely different. 'Aunt Elizabeth is growing' means one thing, but if you add 'old' it will mean another. The substance of what I said was that I now believed superficial organic alteration to be of only temporary benefit when the case was a complicated one; that is to say, when hypertrophies, osseous and cartilaginous growths, etc., were present. Coupled with thorough eradication of these complications, the treatment had been successful in every case treated by me last year, a number of them being partial failures of the preceding year, in which this all-important point had been overlooked."

The Illustrious Vienna Anatomist, Hyrtl, who has for some time been suffering from cataract, has had the right eye operated on by Professor Fuchs, apparently with great success. The left eye is also affected, and will shortly have to be operated on. Professor Hyrtl is seventy-five years of age.

The Berlin Medical Society at the Congress.—A press cablegram, dated Berlin, May 27th, states that a committee of the Berlin Medical Society has considered the suggestion made in certain American quarters that the Society be officially represented at the Medical Congress to be held at Washington. Professor Virchow states that the committee has decided against the suggestion.

New Views as to the Time to Give Cod-liver Oil and Bitters.—It has for years been taught that the best time to give cod-liver oil is from half an hour to an hour after meals. M. Sée, however, claims that it should be given at meals, just after taking soup. It may also be given at night. Bitters, he says, should be given just after meals at dessert—certainly not before meals.

The Position of the Modern Homœopath.—Our able and liberal contemporary, the New York *Medical Times*, makes some statements which are particularly interesting in view of the claims made recently by a Chicago daily paper that homœopathy was a growing force which the bigoted physicians of that great commercial centre would have to recognize. Says the New York *Medical Times*: "We do not believe there is a single member of the faculties of the so-called homœopathic colleges in New York and Philadelphia who do not almost daily administer remedies which in no sense can be called homœopathic. In name they are sectarian, fighting with all their force for a name which binds them to exclusive practice, and yet in the sick-room unsectarian, broad and liberal, bringing to their aid facts and suggestions culled from a large reading of the literature and experience of all schools. Dr. T. F. Allen, at one time one of the most enthusiastic apostles of so called high-dilution homœopathy, now admits that it is unreliable and delusive, and says that homœopathy should be taught in all medical schools, but it should constitute only a part of the course of study. We do not hold that homœopathy is the exclusive and only law of healing."

One of the Largest Medical Fees recorded is that of $40,000 recently paid to Dr. Anderson Critchett for visiting and treating an Indian prince.

Yellow Fever at Key West.—On June 13th there had been twenty-six cases in all at Key West, Fla. One or two new cases appear daily, but it does not seem likely that the epidemic will be an extensive one.

An Oliver Wendell Holmes Hospital is to be established at Hudson, Wis. In a letter accompanying a hymn to be sung at the dedication Dr. Holmes wrote: "I am deeply impressed with the value of a good hospital to a community. I have had the opportunity of knowing a good deal about one such institution, the Massachusetts General Hospital. I have served in this as a house pupil and a visiting physician. I have had friends of both sexes residing in its wards as patients, among them Mr. George Sumner, a brother of the distinguished Senator. I have often thought that I should be very glad, under certain circumstances, to enjoy the privileges of its restful quiet, its skilful physicians and surgeons, and its admirable nursing."

The Milwaukee Veterinarians.—The Milwaukee *Sentinel* says that there is not a horse doctor in that city who would change places with the average family physician. They make from $3,000 to $5,000 a year, or from $15 to $20 a day, and the anxiety they undergo is not half so great as that of the man who has human patients to attend to. They charge $2 a visit, though the ailment be nothing more serious than influenza.

Quite *à propos* is the following from the St. Louis *Republican*: Doctor's office, St. Louis. Enter a lady with a sick dog. "My dear Dr. ——, you must not be angry with me, but won't you please cut off this tumor on poor Fannie's flank?" "Well, madam, I would do anything to oblige you, but this is a little out of my line. Why don't you take the dog to a veterinary surgeon?" "But, doctor, those veterinaries are so expensive. I supposed you could do it just as well."

The Medical College of Ohio and the Cincinnati Hospital.—For a number of years, says the *Lancet and Clinic*, there has been an antagonism between the management of the Cincinnati Hospital and the Medical College of Ohio. The faculty of the latter school was almost unrepresented upon the hospital staff, and as a consequence the students attended only the clinical lectures at the Good Samaritan Hospital, where they heard their own teachers. Recently, however, the Board of Hospital Trustees has lately appointed six members of the faculty of the Ohio College to positions on the staff of the hospital.

The Appeal from the New York Eye and Ear Infirmary.—The appeal of the New York Eye and Ear Infirmary, for contributions to a building fund, is significant not only of the growth of the work of this well-known and long-established charity, but also of the development of that branch of medical science which it specifically represents. It is still true, as it ever will be, that the advancements of any science are the result of the highest talent enlisted in its behalf; but it is certainly less true than formerly that the full measure of success is a purely individual achievement. Science to day furnishes its students with an equipment of which even the best examplers of half a century ago had but dim visions, and chief among these is a knowledge of sanitary aids. Any institution not up to the best in this respect labors under serious disadvantages, and it is because the arrangements of the New York Eye and Ear Infirmary are irremediably defective that the necessity for a new building is so urgent. The older members of the profession need hardly be reminded that Drs. Edward Delafield and J. Kearney Rodgers, half a century ago, represented in their person, the science of Ophthalmology in this part of the world. And when the Infirmary was established by them, it is only truth to say that they were the infirmary, the accessories counting for little. However, what a generation ago was begun by two is now carried forward by half a hundred surgeons, and even so sanguine a man as Dr. Delafield could hardly have imagined such a development as a possibility; and it is due to the self-sacrificing efforts of the founders of the Infirmary that it be maintained at the standard of excellence for which their reputations in their own day and generation were a synonym. This desideratum, however, can now be achieved only by the aids of scientific construction and suggestive laboratory work, and in these respects the present building has to offer only glaring defects and deficiencies. More than fifty thousand patients (old and new) were treated in the various departments of the Infirmary the past year, and above a thousand surgical operations were performed, wherein failure through any fault or shortcoming would have resulted in total blindness. In many instances the skill of the surgeon may have accomplished all that was hoped for, and yet, unless the environment of the case after it leaves the surgeon's hands is such as to prosper his work, the most successful operations will be utterly nullified. Hence the importance that eye hospitals should be in the best sense handmaids to the surgeon's skill; and it is with the view of bringing about a proper and necessary co-operative environment that the appeal of the directors of the New York Eye and Ear Infirmary for a new building has gone out to the public.

The Journal of Hydrotherapeutics is the title of a new monthly journal published in London.

The Largest Dose of Quinine ever given, according to Dr. C. E. F. Knight, of Dublin, was administered by himself in 1883, and was 131.25 grains in twenty-four hours.

New York Post-Graduate Medical School and Hospital.—At the last meeting of the Board of Directors of the New York Post-Graduate Medical School and Hospital, held on May 31st, Dr. Charles Carroll Lee was elected Professor of Diseases of Women. Associate Professor J. R. Nilsen was also elected professor in the same department, to fill the vacancy caused by the resignation of Dr. A. J. C. Skene. Several new instructors were appointed, among them Dr. Joseph O'Dwyer, the inventor of intubation of the larynx. The last year's sessions of the School have been attended by more than two hundred matriculates. The Babies' Ward continues to be well supported by benevolent ladies. The summer session began on June 15th inst.

Professor Billroth, at last reports, was convalescent from his severe illness.

Dr. John Fulton, editor of the Canada *Lancet*, died on May 15th, at the age of fifty years.

Dr. Morell Mackenzie, who has been called in to attend the Crown Prince, is not only an accomplished laryngologist, but a gentleman distinguished for his agreeable social qualities. Dr. Mackenzie believes in specialists and specialism, and not long ago published an article in one of the reviews defending the work of the class which he well represents.

Training-schools for Male Nurses.—A correspondent asks for the address of a training-school for male nurses. There is no such institution in this city, though it is proposed to establish one soon, in connection with Bellevue Hospital. At present male nurses are not trained, but pick up their knowledge in hospitals and elsewhere.

A State Asylum for Insane Criminals is soon to be built in this State, as the last Legislature has appropriated $300,000 for the purpose. The Controller, the the State Commissioner on Lunacy, and Dr. Carlos F. McDonald, Superinteudent of the Auburn Insane Asylum, are commissioned to select the site for the new asylum.

The Rocky Mountains and a Free M.D.—The *Medical Press and Circular* gives publicity to the extraordinary statement that there is a scheme on foot to "whisk off" the intending visitors to the Congress at Washington on an enticing excursion to the Rocky Mountains and elsewhere. The promoters of this novel project are, of course, the same persons who have in other ways endeavored "to minimize the success of the Congress." We are at a loss to know where the *Press* got hold of such a silly fancy. Quite comparable with it is its hint that honorary medical degrees will probably be conferred on some of the visitors, and it adds that doubtless the prospect of acquiring an M.D. on easy terms would act as a substantial "draw."

Death of Professor Boussingault.—The death is announced from Paris of the eminent French chemist, M. Joseph-Dieudonné Boussingault. The deceased, who was born in 1802, occupied the chair of Agriculture in the Paris Conservatoire of Art and Industry. M. Boussingault was the author of a large number of papers on physics and chemistry, and of treatises on "Chemistry and Physiology in Agriculture." His name is familiar to all medical students through his feeding experiments, in which he deprived animals of salt.

Reports of Societies.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

Second Annual Meeting, held at Washington, D. C., June 2 and 3, 1887.

(Continued from page 668.)

FRIDAY, JUNE 3D—SECOND DAY—MORNING SESSION.

DR. E. T. BRUEN, of Philadelphia, read a paper on

BERGEON'S METHOD OF TREATING PHTHISIS.

Since February last he had employed Bergeon's method of treatment in sixty-one cases. Forty-four of these cases had been benefited, but of these only three appeared to regain full health. Two of these were cases of incipient phthisis, with apparent consolidation of the apex of the right lung. In one of these cases the bacillus tuberculosis was not found, although five examinations were made. In the other case the bacillus was found. In these cases the apparent recovery had been associated with a decided increase in weight. He believed, however, that the disease was simply latent. The third case was one of broncho-pneumonia. In all the other cases the lesions were more or less advanced, with the presence of cavities and profuse expectoration. In the fifteen cases in which a negative result was obtained the treatment in some was followed by temporary benefit. The good results had consisted in lessening of the expectoration, diminution of the cough, lowering of the temperature, and suspending of the night-sweats. In most of the cases there was a diminution of from fifteen to twenty beats in the pulse, and a diminution of half a degree in the temperature, during the administration of the gas. Even in those cases which were benefited, and in which the temperature had been brought to normal, there would be during the progress of the treatment occasional outbreaks, with a return of the fever and the other symptoms. These, however, disappeared under a continuance of the injections. In order to determine the effect of the treatment on the bacilli, Dr. E. O. Shakespeare made a number of examinations during the progress of the cases. There had been no diminution in the number of the bacilli. It was, however, thought that in those cases where the treatment had been continued for some time the reaction of the bacilli to the staining fluid was less marked.

Two cases had died. In one of these an autopsy was made. This case had been under treatment for two months. The walls of the cavity were moderately smooth and firm, but there was no tendency to cicatrization. The results were of a decidedly negative character.

In most of the cases a solution made by the addition of five grains each of sodium sulphide and sodium chloride to a pint and a half of water was the solution employed. In some cases the strength of the solution had been gradually increased, but where no benefit had been obtained from the weak solution the stronger solution did not act with any better results.

In cases of diarrhœa his experience had been unfavorable, except where the gas was given in very small quantities. Chronic peritonitis was a contra-indication to the use of this plan of treatment. In about one case in every ten he had observed the reaction of sulphuretted hydrogen when a paper treated with acetate of lead had been applied to the mouth.

Bergeon's method is chiefly valuable in those cases attended with bronchial catarrh. He had had very little good effect in those cases where there was thickening of the lung without much catarrh. The speaker feared that the trouble and detail necessary to the successful application of this method and the limitations of its power would cause it to be set aside for other therapeutic measures.

DR. F. C. SHATTUCK, of Boston, presented some

CLINICAL NOTES ON BERGEON'S METHOD OF TREATING PHTHISIS.

The speaker had treated only seven cases by this method. They were in an advanced stage of the disease. He had seen such improvement follow careful dietetic and hygienic management that he had not much confidence in the results claimed for special methods of treatment in these cases. Any new method of treatment will often have an apparently beneficial effect through its influence on the mind even in those case which are incurable. Six of the cases treated suffered with phthisis, and five were in an advanced stage of the disease. One was a case of chronic bronchitis with asthma and emphysema. Four of the patients suffered with more or less pronounced collapse from the use of the injections. Nausea, vomiting, and diarrhœa occurred in several cases. In one case, although the patient was weak, no local or general ill-effect was observed. In another case the treatment was continued four weeks with no ill-effect. The only benefit obtained was a diminution of the expectoration. In the case of asthma and chronic bronchitis, thirty-four enemata were given. The improvement was no more rapid than on a previous occasion when the patient had been treated in the same general way with the exception of the gas. He presented the following conclusions:

1. Toxic symptoms may follow the injection of sulphuretted hydrogen gas; these are nausea, vomiting, general depression, collapse, and perhaps headache.

2. Strong artificial solutions of sulphuretted hydrogen gas with carbonic-acid gas are apt to cause abdominal discomfort. The risk of this is diminished by heating the solution of the former gas.

3. This is not by any means a specific. If useful at all it is only as an auxiliary to the more usual methods of treatment.

4. The only benefit which we have seen that could be fairly attributed to the enemata was a diminution in the amount of the expectoration.

In conclusion, the author stated that the impression which he had formed was that the good results which had unquestionably followed this method of treatment were attributable in large part to the stimulation induced by the employment of a novel method of treatment which makes the patient feel that something is being done for him.

DR. WILLIAM PEPPER, of Philadelphia: I have, with the assistance of Dr. J. Crozier Griffith, employed this method in 24 cases in which the treatment was continued, on an average, twenty-five days. Other treatment was frequently combined with the use of the injections. A daily temperature record was kept in 16 cases: In 4 there was more or less reduction; in 11 there was no appreciable effect; in 1 the temperature increased, but this was probably a coincidence. In no case was the temperature brought from a febrile to a continuously normal condition. The fall was not more than is seen in similar cases under other methods of treatment.

In 20 cases in which the weight was recorded there was in 8 more or less gain. Eight pounds in thirty-seven days was the greatest gain. In 6 cases the weight remained stationary, and in 6 it was diminished.

The improvement in cough was not marked. The expectoration was somewhat diminished in 4 out of 24 cases. Search was made for the bacilli in 30 cases and they were found in 27. In 11 cases the examination was repeated, and only in 4 was there any apparent decrease. Cases of night-sweats were not numerous. In 1 they were checked and in 7 improved. Physical examination showed no improvement in a single case. The enemata had a decided hypnotic influence in 3 cases. The only unpleasant symptom of any real moment was colic. This was complained of in 11 out of 24 cases. Three others suffered so much that

the treatment could not be repeated. The colic was not often controlled by giving smaller quantities of the gas, nor did it seem to be influenced by the slowness of the injection. This method of treatment is seldom of real benefit, although it is occasionally of benefit by relieving certain symptoms.

Dr. H. C. Wood, of Philadelphia: After studying the cases treated by this method I came to the conclusion that it was of a certain amount of benefit. I saw that the method of employing the gas presented many objections. The sulphuretted hydrogen should accomplish the same results when absorbed by the stomach as when taken up by the large intestine. I have, therefore, administered the sulphuretted hydrogen gas in carbonic-acid water. Water at the ordinary temperature takes up two or three times its volume of sulphuretted hydrogen. I think that this is a distinct addition to pulmonary therapeutics. I have tried it in certain cases with benefit.

Dr. Beverley Robinson, of New York: This method is a valuable adjunct to our methods of treatment. The pain which is experienced in many cases may be due to the fact that there are ulcerations in the intestine. These may be present without the existence of diarrhœa.

Dr. George L. Peabody, of New York: I have followed all the details of this method of treatment as given by Bergeon, and have used the water of Aubon, which he recommends. My results have not been materially better than those of the gentlemen who have preceded me.

Dr. F. Forsheimer, of Cincinnati: I have performed the following experiments: I have treated two or three patients in the way recommended for some time. Then I have substituted for the sulphur solution plain water and continued the injections for a time. I have also given the carbonic-acid gas by injection; and, lastly, I have for two weeks treated these cases with the injection of air, using the Bergeon apparatus. The patients in these experiments of course did not know that any change had been made in the gas employed. As far as I have been able to judge, the patients treated with air did about as well as those treated with sulphuretted hydrogen.

Dr. James T. Whittaker, of Cincinnati: I have used the sulphuretted hydrogen gas both by injection and also by inhalation. The effects under both methods of administration seem to be the same. It mitigates the cough, relieves the fever, and lessens the night-sweats. It, however, is not a specific.

Dr. F. P. Kinnicutt, of New York, read a paper on

ATROPHY OF THE GASTRIC TUBULES—ITS RELATION TO PERNICIOUS ANÆMIA.

The speaker gave the histories of two cases in which the typical symptoms of pernicious anæmia were well-marked. At the autopsy in each of these cases nothing special was found in any organ but the stomach. The inner surface of the organ was smooth. Microscopical examination was made of numerous sections removed from different parts of the stomach. Through a large extent no trace of gastric tubules was found; in some parts the more superficial portions of the tubules could be found, but the deeper portions could nowhere be made out. There was also seen a peculiar hyaline substance in the shape of tubes and of drops. Numerous irregular cells were seen near the surface of the mucosa. The author thought that in this lesion of the stomach was to be found the explanation of a certain number of cases of pernicious anæmia.

Dr. Francis Delafield, of New York: In a number of cases marked changes in the mucous membrane of the stomach have been found. The main question is whether the lesion of the stomach is to be looked upon as a cause or as the result of the pernicious anæmia. For myself, I look upon the lesion of the stomach as secondary and not primary.

Dr. F. P. Henry, of Philadelphia: The cases reported by the author, taken in connection with other cases which have been recorded, demonstrates that there is a form of anæmia associated with, and I think dependent upon, atrophy of the gastric tubules. That this condition is primary and not secondary is, I think, sufficiently attested by the fact that it is not found in any other condition. Such an extreme degree of atrophy has not been found in any other condition with which I am acquainted. In the case reported by Dr. Osler and myself there was complete absence of the peptic glands. It was impossible that any form of gastric digestion could be accomplished.

Dr. William Osler, of Philadelphia: There is unquestionably a group of cases of pernicious anæmia, in which there are serious lesions of the gastric mucous membrane, although these lesions are not always the same. I think that it is quite impossible to distinguish clinically the cases with gastric atrophy from the cases without these lesions.

Dr. E. C. Seguin, of New York, presented

A THIRD CONTRIBUTION TO THE STUDY OF LOCALIZED CEREBRAL LESIONS.

One case reported related to the location of the facial centre. The patient, a boy of seven years, was first seen in January, 1885. He had been complaining of numbness in the right hand. The right leg and arm were slightly paretic. There was no headache and no aphasia. Shortly after this clonic convulsive movements occurred in the right cheek and both eye-balls were turned to the right. This lasted for over two hours. At times the speech was thick. There was no history of serious injury, and there was no evidence of pulmonary, renal, or arterial disease. There was no cranial tenderness on pressure. The tongue, when protruded, deviated to the right. The diagnosis was meningeal adhesion over the precentral region. Iodide of potassium was given in gradually increasing doses until from sixty to seventy-five grains were taken. Early in April of the following year symptoms of tubercular meningitis developed and the child died after an illness of three weeks. At the autopsy the ordinary lesions of tubercular meningitis were found. In addition there was a patch of adhesion situated over the left precentral gyrus and the caudal part of the second frontal gyrus. This was one inch in diameter, and would indicate that in the human brain the facial centre is in the caudal end of the second frontal convolution. The second case related to the situation of the leg-centre. A patient, aged forty-nine, suffered with paresis of the right leg and clonic spasm of the right abdominal muscles. There were right hemi-epileptic attacks, the spasm beginning in the abdominal muscles and extending to the arm and leg. These attacks were repeated without loss of consciousness. Paralysis of the right leg and paresis of the right arm developed. There was no aphasia and no choked disk. Attacks of a syncopal character occurred, in one of which the patient died. At the autopsy a large sarcomatous tumor was found involving the cortex of the paracentral-region gyrus. Two small nodules were found in the white substance below the principal tumor. This would indicate that the nerve-centre for the leg was in the paracentral lobule.

Dr. James J. Putnam, of Boston: I would report a case recently under my care. A man of forty-five suffering with locomotor ataxia, probably of syphilitic origin, suddenly developed convulsions of the right arm and leg without loss of consciousness and without change in the voice. The symptoms relating to the arm entirely passed away, but the leg never recovered its normal condition. The patient died some time later and at the autopsy a small hemorrhage was found at the lower edge of the paracentral lobule.

Dr. F. T. Miles, of Baltimore: A patient suffering with Bright's disease suddenly became hemiplegic without the voice being affected. The arm and leg were

affected. He rapidly improved, but the leg remained weak. He complained a great deal of a dragging in the shoulder. At the autopsy the only lesion that could be found was a hemorrhage of the size of a bean in the para central lobule.

Dr. H. M. Lyman, of Chicago: Some months ago I saw a case in which there was a sudden convulsion without loss of consciousness, the left arm being principally affected. These convulsions were repeated. There was a paretic condition of the left arm, which in a few days extended so as to involve the corresponding leg. The convulsive movements of the upper extremity continued to recur. They did not involve the face. The patient died, and a sarcoma was found on the right side occupying the position of the centres for the arm and leg.

Dr. James J. Putnam read a paper on

THE FREQUENCY WITH WHICH LEAD IS FOUND IN THE URINE, AND ON THE SYMPTOMATOLOGY OF CHRONIC LEAD-POISONING,

which consisted in an analysis of eighty-six cases in which the urine had been examined for lead, although no unequivocal signs of lead-poisoning were present.

Of the 86 cases in which the urine was examined, lead was found in 48, and was absent in 38, and there is good reason for believing that the number of cases in which it was found in the urine does not fully represent the whole number in which it was present in the body. If from the 48 cases in which lead was found we subtract those where the patients were known to have been strongly exposed by their occupation or otherwise, we have left 32, to be contrasted with 38, as approximately representing the ordinary exposure of the community. Taking the evidence furnished by the cases themselves, and seeking to indorse it by testimony drawn from the literature of the subject, by the effects of treatment, we arrive at the following conclusions, which are, of course, to be regarded as provisional:

1. It is probable that lead may cause neurasthenic symptoms, which may exist for a long time without other signs of poisoning.

2. The same is true of fine muscular tumor, especially if associated with debility.

3. The most important conclusion is, lead seems to cause occasionally a greater or less degree of the symptoms classed as spastic paraphigia, instead of the usual type of paralysis with atrophy and loss of the deep reflexes.

4. Additional evidence is furnished of the importance of suspecting lead as a cause of vague cerebral symptoms, such as are often due to syphilis.

5. In one case of epilepsy in a person not predisposed and where the probable first attack occurred at the age of twenty-five, besides the discovery of lead in the urine, there was a slight weakness and impairment of electrical reaction of the long extensors of the fingers.

Two cases of ataxia, with extensive muscular atrophy and other signs of peripheral neuritis, were reported, probably due to lead. Cases were reported in which the poisoning had been produced by working in the manufacture of rubber.

Dr. I. E. Atkinson, of Baltimore, read a paper entitled

FORMS OF TYPHOID FEVER SIMULATING REMITTENT MALARIAL FEVER.

The object of the present paper was to describe forms of typhoid fever in which all the usually characteristic symptoms are absent except mild fever. These cases commonly occur during the late summer and early autumn. They begin with a chill or insidiously and assume a course of a mild remittent type, never passing into a typhoid condition, never developing the characteristic symptoms of typhoid, yet absolutely uninfluenced by antiperiodic treatment. They last three, four, or even five weeks, and almost always end in slow lysis and recovery. They resemble malarial conditions, except in the persistence of fever under strongly antimalarial treatment, and in the occasional concurrence of circumstances pointing to a typhoid origin. There is no hebetude, the patient sleeps well, the tongue is slightly coated, there is almost never epistaxis, constipation is commonly observed, there are no bloody stools, no tympanites, no iliac tenderness or gurgling, and rose-spots are usually absent. The patient is bright and cheerful. The more severe cases after beginning as remittents may gradually evolve typhoid symptoms. Three cases were reported showing the type of fever described occurring under conditions indicating their typhoid origin. While typhoid fever is one of the most characteristic of diseases, its special symptoms are very inconstant. There is not a sufficient realization of the mildness with which it often runs its course. Walking typhoid, although usually considered rare, is in reality frequent. Cases in which sudden accidents reveal their true nature are probably but a small portion of the whole number. Our views of typhoid fever have been largely modified. Low ranges of temperature are now often encountered. Straube and Fraentzel and others have reported severe forms of the disease with high mortality, although the temperature did not attain 102.2°. Normal and even subnormal temperatures are sometimes maintained throughout the attack. In mild cases a slight degree of fever-heat is not at all uncommon. Liebermeister and others report such cases. Loomis treats "mild typhoid" with walking cases, and states that the eruption appears early and is scanty and brief, and that a diarrhœa is present in most cases. This is true of many cases, but there is a large class in which constipation is the rule and rose-spots the exception—much larger than is generally admitted. Liebermeister and others describe interesting examples. Dr. W. W. Johnston has most accurately described similar cases occurring in Washington. Malaria often complicates typhoid fever, but it oftener happens that its presence is assumed unjustifiably. A mental bias in favor of malaria is often strongly pronounced in the face of the strongest contrary evidence. The diagnosis of these cases from remittent malarial fever often rests upon the crucial test of treatment. It is admitted that occasionally antiperiodic remedies fail to control the malarial paroxysm, especially in pernicious and adynamic forms. In milder forms the behavior under quinine practically solves the difficulty. Where the full administration of the antiperiodic remedy for a number of days fails to terminate the attack, the diagnosis of typhoid fever becomes justifiable, and the prognosis can be made with a high degree of confidence. Not often earlier than the second or later than the fourth week the fever will terminate almost constantly by lysis, rarely by crisis.

Dr. William H. Draper, of New York: I see many cases in New York which have been diagnosed as typho-malarial fever which I consider to be cases of typhoid fever. I think that the diagnosis of typhoid fever can be usually made in the course of the first week of the disease by attention to the characteristic course of the fever. The nervous symptoms of typhoid fever are of great importance in the diagnosis. In considering a disease like this we should study it in its totality and not in its elementary parts. Dr. Atkinson has spoken of the aid given by quinine in the diagnosis. My own experience confirms that of others with reference to the use of quinine as an antipyretic in typhoid fever. Unless used in such doses as to produce a certain degree of collapse it is useless; I believe that it does nothing more than to increase the discomfort of the patient. If in five or six days the use of quinine does not succeed in checking the fever we may conclude that we are dealing with a continued fever of the nature of typhoid.

Dr. John Guiteras, of Charleston: From my observation I have come to a conclusion different from that

expressed by the author. These cases present no symptom of typhoid fever with the exception of the continued fever. They are so numerous as we go farther south that I would class them as a separate disease. I have examined some of these cases of prolonged continued fever of southern countries post-mortem and have failed to find the lesions of typhoid fever. My view of this fever is that it belongs to the class of functional fevers. A simple continued fever may be set up by an excessive demand made upon any of the important functions of the body. I have thought that in warm climates where constant exertion was required on the part of the heat-centres to keep within limits the production of heat a paralytic condition of these centres might be induced, especially toward the close of a long and hot summer.

Dr. A. Jacobi, of New York: There is one aid in diagnosis which I have not heard alluded to, and that is the urine-test of Ehrlich. This has frequently been of much service to me. It is prepared as follows:

Solution No. 1: Sodium nitrite, 1 part; water, 200 parts.

Solution No. 2: Sulfanilin acid, 5 parts; concentrated muriatic acid, 50 parts; water, 1,000 parts.

Add one and one-fifth parts of the first solution to fifty parts of the second.

Equal parts of this mixture and the urine are to be mixed. Then add about sixty or seventy per cent. of aqua ammonia. In normal urine there will be only a slight discoloration, while in urine from typhoid fever it will be deep purple. This test is rarely applicable during the first two or three days. It generally can be applied up to the fifteenth or eighteenth day. It should also be stated that in cases of acute miliary tuberculosis the same reaction is obtained.

Dr. R. H. Fitz, of Boston: An epidemic of an anomalous form of fever recently occurred in Boston among a number of emigrants. The diagnosis lay between typhoid and typhus fever. It was concluded that they were cases of typhoid fever. One case ended fatally. The intestinal lesions were of the most trivial character. The enlargement of Peyer's patches was no greater than is seen in many cases of enteritis. The lesions were so superficial that it seemed quite probable that they would have disappeared if the case had lived a few days longer.

Dr. Israel T. Dana, of Portland: Some of the cases to which Dr. Fitz has referred found their way to Portland and one of them died there. The autopsy in this case showed well-defined but not complete lesions of typhoid fever. I believe that this is what will generally be found—that the atypical cases will present lesions as imperfectly developed as the symptoms.

Dr. W. J. Councilman, of Baltimore: I think that a simple examination of the blood will enable us to differentiate between the continued malarial fevers and typhoid fever. The organisms found in these cases of continued malarial fevers are very easy to recognize.

Dr. William Osler, of Philadelphia: I agree with the last speaker, that we have in the microscopical examination of the blood a positive means of diagnosis. I have no doubt that in these doubtful cases a careful examination of the blood will determine whether they are malarial or not, while a careful examination by culture methods will determine whether or not it is a case of typhoid fever.

EXECUTIVE SESSION.

The report of the Committee on the Congress of American Physicians and Surgeons was received and adopted, and Dr. William Pepper, of Philadelphia (with Dr. Reginald H. Fitz, of Boston, as alternate), was appointed as the representative of this Association.

OFFICERS FOR THE ENSUING YEAR.

President—Drs. William H. Draper, of New York.

Vice-Presidents—Drs. Francis Minot, of Boston, and J. Palmer Howard, of Montreal.

Recorder—Dr. William Osler, of Philadelphia.

Secretary—Dr. Henry Hun, of Albany.

Treasurer—Dr. W. W. Johnston, of Washington.

The following were elected to active membership: Drs. A. V. Meigs, Louis Starr, and J. H. Musser, of Philadelphia; Dr. James E. Reeves, of Wheeling, W. Va.; Dr. William H. Whitney, of Boston; Dr. James Stewart, of Montreal, and Dr. M. Allen Starr, of New York.

Dr. John S. Billings, of Washington, was elected to honorary membership.

Adjourned.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fourth Annual Meeting, held in the Johns Hopkins University, Baltimore, Md., May 31 and June 1, 1887.

TUESDAY, MAY 31ST—FIRST DAY—AFTERNOON SESSION.

The Society was called to order by the President, Dr. Frank Donaldson, Sr., of Baltimore.

PRESIDENT'S ADDRESS—PROPHYLACTIC TREATMENT OF THOSE WHO INHERIT A PREDISPOSITION TO PHTHISIS.

He referred to the great mortality of phthisis, but certain statistics compiled in this country and abroad show a decrease in the annual mortality. In England there has been a gain in males of fourteen per cent., and in females of twenty-two per cent.; in Massachusetts there has been a gain of fifty-four lives per hundred thousand. Thirty per cent. of the cases have an inherited predisposition to the disease. The hereditary form, when developed, offers the least prospect of recovery. Reference was made to the pathology of the disease. Five years have elapsed since the contagion of tuberculosis was alleged to have been discovered, and nearly all observers have now confirmed the views of Koch. There is abundant evidence that human subjects readily yield to the bacillar poison when previously they have been in perfect health. The bacillus is always present in phthisis, and we must accept it as the full explanation of the manifestations of tuberculosis. The disease may be propagated by the inhalation of the dried bacillus from the expectoration of diseased persons by persons predisposed to tuberculosis. The various theories which had been advanced to explain heredity were discussed. The prophylactic treatment embraces two elements: (1) The improvement of the general health of the subject, and (2) the protection from contagion. The tuberculous mother should not nurse her child, but, if possible, it should be given to a healthy wet-nurse. The hygiene of the nursery should be looked after carefully. The room should be well ventilated, and kept at a comparatively low temperature. The subject should live much out of doors, especially between the ages of fifteen and twenty years. The beneficial influence of sunlight should be borne in mind. All causes of glandular irritation should be avoided. Scrofulous glands should be dispersed or removed. The physical form of the chest should be enlarged by gymnastic movements. If possible, life should be passed in high altitudes. Oleaginous fluids are useful if they can be digested. The milk and flesh of tuberculous animals must be avoided, for cooking rarely destroys the bacilli of beef. If the prophylactic treatment is thoroughly carried out, the hereditary proclivity may remain latent, and the individual never contract the disease.

Dr. James R. Leaming, of New York, read a paper entitled

THE PHILOSOPHY OF CLIMATIC TREATMENT OF DISEASES OF THE CHEST.

It is observed that the greatest improvement takes place during the first three weeks of the patient's stay at a new place. The suggestion was made that a line of resorts be established along the Atlantic sea-coast. The

patient could begin in the summer at the most northern and gradually pass southward, making a stay of a few weeks at each place. Having completed the series, the patient may return, taking the stopping-places in a reverse order. This same plan might be applied to the Pacific coast and to the mountains. The speaker also suggested the propriety of state and municipal authorities furnishing sanatoriums for the benefit of those unable to avail themselves of the advantages of existing institutions.

Dr. R. G. Curtin, of Philadelphia, read a paper on

THE INFLUENCE OF SEA-AIR ON SYPHILITIC PHTHISIS.

The speaker gave in detail the histories of five cases of what appeared to be syphilitic phthisis in which improvement followed prolonged sea-voyages, and in each case the symptoms returned when the patient again took up his residence on land. He was led to consider the cases observed as cases of syphilitic phthisis, for the reasons that there were no symptoms of chronic pneumonia preceding the attack, that the lung-trouble followed syphilitic infection with constitutional symptoms, that the disease was influenced to some extent by constitutional treatment, and that there was no tendency to tuberculosis in these cases. He referred to the observations of Dr. William Porter, who relies upon the following points in reaching a diagnosis of syphilitic phthisis: 1, Abundant expectoration without signs of softening; 2, a debilitated condition, without marked emaciation, and a rational history of phthisis; 3, pronounced dyspnœa, without evidence of cardiac or pulmonic obstruction to the circulation; 4, pain along the sternum and the tibial crests; and, 5, the satisfactory response to treatment. Dr. Porter had examined the sputa in one hundred cases without finding the bacillus. The speaker was not prepared to say why it was that the sea-air proved beneficial in these cases, while in most of the ordinary cases of phthisis residence on the sea-coast was not desirable.

A paper on "Diseased Conditions for which Sea-air is of Doubtful Benefit," by Dr. Boardman Read, of Atlantic City, was read by title.

DISCUSSION.

Dr. E. T. Bruen, of Philadelphia: It is probable that in syphilitic phthisis the benefit of the sea-air is due to its influence on the catarrhal processes. In catarrhal affections of the mucous membranes in general, it has seemed to me that residence at the sea-shore was useful. On the other hand, in tubercular phthisis it has seemed to me that the influence of sea-air was disastrous. I have found that those cases benefited by prolonged sea-voyages are those in which there is no inherited tendency to tuberculosis.

Dr. V. Y. Bowditch, of Boston: I should make a great distinction in speaking of the sea-coast air and the pure sea-air. Cases which could not stand the harsh, cold, and changeable air of the sea-coast may be benefited by a sea-voyage or residence on an island some distance from the shore where the conditions are similar to those which are obtained in a sea-voyage.

Dr. F. I. Knight, of Boston: While I am sure that the general feeling is that the coast climate is not suitable for cases of phthisis, yet in several instances I have known patients to improve and gain in weight during a stay at some of the coldest resorts on the New England coast.

Dr. James C. Wilson, of Philadelphia: With reference to residence at the sea-coast in the treatment of phthisis, I would say that, in my experience, there are three classes of patients with consumption who cannot go to our exposed Atlantic sea-coast without risk. These are, first, those in whom there is active febrile disturbance; secondly, those of a highly excitable and nervous organization; and, thirdly, those who suffer from repeated attacks of spitting of blood. Such patients cannot safely reside for any length of time on the Atlantic sea-coast.

Dr. Frederick C. Shattuck, of Boston: The author has referred to syphilitic phthisis; that is to say, a destructive process in the lung, not due to tubercle, but to the syphilitic virus. It seems to me to be a difficult matter to determine whether or not there is such an affection. Tubercular phthisis varies so much in its symptoms that the points mentioned, I think, cannot be relied on. It seems to me that the criterion would be the presence or absence of the tubercle-bacillus. The fact that the bacillus is not found is no proof that it is not present. The German Committee on the Collective Investigation of Disease studied this matter last year, and came to the conclusion that so-called syphilitic phthisis had no real existence. Both syphilis and tuberculosis are common diseases, and the one offers no immunity from the other, so that we should expect to frequently find them combined in the same individual.

Dr. J. H. Musser, of Philadelphia: In my experience in the post-mortem room I have come across only one case in which the lesions bore any resemblance to what we should expect to find in syphilitic phthisis. This was the case of a young man with syphilis, and cirrhosis of the liver due to syphilitic interstitial hepatitis. There were also syphilitic gummata in the brain, and the patient died of syphilitic meningitis. There were scattered through both lungs innumerable miliary granules, not at all resembling miliary tubercles. These were solid bodies made up of a yellow core which was moderately firm and surrounded by a ring which made up at least one-half of the nodule. The microscopical examination showed these bodies to consist of a ring of firm fibrous connective tissue, in the centre of which there were degenerating cells. We were unable to find the bacillus of phthisis, but, as has already been stated, the failure to find it is no proof of its absence. I should not call this a case of syphilitic phthisis, but rather a case of syphilis of the lungs.

Dr. E. Fletcher Ingalls, of Chicago: I apprehend that most of us have seen cases in which the syphilitic nature of the disease admitted of no question. Even if the bacilli are found, it would be no proof that the case had not originated as a syphilitic trouble and that it had subsequently become tubercular. I recall one case in which the syphilitic manifestations were very prominent. There was consolidation of the lung, particularly of the middle portion of one lung. There was a history of syphilis, and distinct cutaneous lesion. The patient had been in Colorado and returned much worse. On his return to a lower altitude he was put on the use of iodide of potassium, and ultimately apparently recovered.

The papers were also discussed by Drs. Ford, of Utica, and Frank Donaldson, Jr., of Baltimore.

Dr. J. H. Musser, of Philadelphia, read a paper entitled

THE TREATMENT OF THE FINAL STAGE OF PHTHISIS.

The paper consisted of a detailed account of the symptoms met with in the last stages of phthisis, and referred to the various measures which he had found useful in these cases. To relieve the high temperature, he had resorted to antifebrin with advantage. Quinine was found to act unsatisfactorily.

The President announced as the Nominating Committee, Drs. F. C. Shattuck, E. T. Bruen, Willis E. Ford, B. F. Westbrook, and W. H. Geddings.

Adjourned.

Evening Session.

Dr. Frank Donaldson, of Baltimore, read a paper entitled

CAUSES OF CARDIAC FAILURE IN HIGH ALTITUDES.

The important fact that there is often great dyspnœa and sudden cardiac failure on going to high altitudes has not been sufficiently emphasized. Many patients are sent, for general or special reasons, to high altitudes, and are thereby done great injury, especially if they suffer

from any form of functional or organic heart disease. From some experiments with the pneumatic cabinet, the author had come to the conclusion that this treatment should not be employed in cases in which there is any valvular disease of the heart or fatty degeneration of its walls. Before being subjected to treatment in the cabinet, an examination of the heart should always be made. It has been asserted that the cause of the cardiac failure in ascending to high altitudes is want of oxygen. The speaker had performed certain experiments with reference to this point. At altitudes within ten thousand feet there is sufficient oxygen to supply the hæmoglobin. In ascending to high altitudes the pressure of the air within and without the lungs is the same, but on the heart the action is different. The pressure is removed from the outer surface of the heart, while the internal blood-pressure remains the same. There consequently must be dilatation of the heart-walls. This, in the author's opinion, was the cause of the heart-failure under these circumstances.

DISCUSSION.

Dr. B. F. Westbrook, of Brooklyn: I have no doubt that the explanation of the author with reference to the effect of high altitudes on the heart is correct, but in the pneumatic cabinet the conditions are different. As a matter of practical experience, I have found that patients with mitral stenosis, or mitral regurgitation with pulmoary congestion, can be put into the cabinet with safety. I should hesitate very much before putting a patient with aortic regurgitation into the pneumatic cabinet. In mitral disease, however, the tendency is to assist rather than exhaust the diseased heart.

Dr. H. F. Williams, of Brooklyn: Certain New York observers have claimed that in weak heart, particularly the tobacco heart, they have obtained with the pneumatic cabinet an effect similar to that of digitalis, due probably to a stimulation of the circulation through the coronary arteries.

Dr. S. S. Cohen, of Philadelphia: The inhalation of compressed air in cases of dilated heart has been recommended by Waldenburg and others. I have recently employed this measure with beneficial results in alleviating the dyspnœa and defective circulation due to a dilated heart.

Dr. James T. Whittaker, of Cincinnati: The condition met with in a rarefied atmosphere cannot be compared with that met with in the pneumatic cabinet. It does not seem possible to exert any mechanical pressure upon the heart in the cabinet. This is one of the most efficacious means of treating irregular heart. I have used the cabinet for two years and have seen no ill effects from its use, although I should not subject a patient with advanced cardiac disease to this plan of treatment.

SOME HOSPITAL CASES OF PHTHISIS; MARKED IMPROVEMENT UNDER GENERAL TREATMENT, WITH SPECIAL REFERENCE TO ALIMENTATION,

was the title of a paper by Dr. F. C. Shattuck, of Boston.

The cases reported had been treated in the Good Samaritan Hospital of Boston, which is devoted to the care of chronic disease. Many of the patients had been exposed to unfavorable hygienic surroundings. The treatment employed was devoted largely to improvement of the general condition. Search had been made for a specific treatment. If the disease is of a parasitic nature it is natural to suppose that such a treatment would be of avail. At present no such method of treatment is known. There are few individuals to whose lungs at one time or another the bacillus does not gain access. The fact that certain individuals are affected while others escape forces us to believe that there is a predisposition to the disease. The treatment employed by the author had consisted in relieving symptoms, improving the digestion, and the administration of as much food as the patient could take in the natural way. Artificial feeding had not been resorted to, but the patient was fed six or seven times a day. From two to ten raw eggs, with milk, were given daily to each patient. Alcoholic stimulants were not administered to these patients as a routine treatment, but were used only temporarily for special purposes. He had for several years been systematically cutting down the quantity of alcohol used in chronic cases, and had seen no reason to regret it. His experience had been that alcohol was not used with sufficient discrimination in chronic cases of disease. Beef, milk, eggs, and other nourishing articles are more expensive than alcohol, but if they can be consumed in sufficient quantity they are more useful. In 1883 the amount expended per patient for alcoholic liquors had been $2.70, while in 1886 it had been only thirty-four cents. The patients received no injury, even if they were not benefited by this reduction. Eight cases of well-marked phthisis were reported in which a decided gain in weight and general improvement resulted from the employment of the plan of treatment above described. About sixty cases had been under treatment.

Dr. E. T. Bruen, of Philadelphia, read a paper on

GASEOUS ENEMATA.

Of the therapeutic measures under the control of the profession, diet, climate, and suitable hygiene are of principal importance. It is possible by climatic and dietetic treatment to so change the nature of the tissues that they shall not be suitable culture-media for the growth of the bacillus of tuberculosis. I wish, however, to refer more particularly to the use of the Bergeon method by the injection of sulphuretted hydrogen. To antagonize the specific cause of the disease this method has been a failure so far as my experience goes. Since February last I have had under treatment sixty-one cases by this method. Systematic examinations of the sputa have been made by Dr. E. O. Shakespeare. There has been no apparent reduction in the number, or change in the character, of the bacillus. This method should be classed among the methods at our disposal for the treatment of this disease. The good effects in my hands have been reduction of temperature, reduction of expectoration, very often a complete suppression of bronchial catarrh, and relief of cough. This leads to improved digestion, and enables the dietetic treatment to be carried out with great thoroughness. Forty-four of these cases showed improvement to a certain extent, the average gain in flesh being about five pounds. In one-half of the cases the temperature has been brought to the normal, while in the remainder, although the temperature has not been brought to normal, it has been reduced two or three degrees. In fifteen cases the results have been negative, but in no case did any harm follow the use of this plan of treatment. The improvement has been most marked where there is considerable catarrhal element. Those cases in which there has been more or less thickening of the lung, with the general symptoms well marked, wasting, loss of flesh and weight, without much rise of temperature, I have found were not specially benefited by the injection of gas. I have had the opportunity of making a post-mortem in one case which had been subjected to this treatment. Although the cavities in the lungs were unusually clean, I did not observe any evidences of cicatrization. With reference to the strength of the solution, I have not found strong solutions at all satisfactory. The best results have been obtained from a solution of five grains of sulphide of sodium with five grains of chloride of sodium in one and a half pint of water. I have never found it desirable to administer more than a gallon and a half of gas at one time. I insisted that the injection be made slowly, and that one-half to three-quarters of an hour should be occupied. I have not derived as much satisfaction in the treatment of the various forms of phthisis to which I have referred from any method as I have from the injection of

sulphuretted hydrogen. I have always tested the breath for the presence of sulphuretted hydrogen. I have had negative results in at least eight out of every ten cases.

Dr. S. S. Cohen, of Philadelphia: Dr. J. Solis-Cohen and myself have obtained the most decided benefit from strongly impregnated waters. The best results were obtained in those cases in which the patient had a decided taste of sulphuretted hydrogen, which continued for two or three hours after injection. The best effect has been obtained in those cases in which suppuration is about beginning. In about fifty per cent. of the cases the condition has been greatly ameliorated. In another twenty-five per cent. there was slighter amelioration, while in the remaining twenty-five per cent. there was more or less benefit to certain symptoms. I have seen no case in which no results were obtained.

Dr. James T. Whittaker, of Cincinnati: I have for a month used sulphuretted hydrogen by inhalation, having previously employed it for a month by injection. It has produced no unpleasant results in any case. The effects obtained have been about the same as those resulting from injection. I have found records of only two in which fatal results followed. It has been asserted that the good effect is due to the carbonic acid, but I am entirely incredulous of the effect of this agent.

Dr. Roland G. Curtin, of Philadelphia: It has been recommended by Dr. H. C. Wood that the sulphuretted hydrogen be taken by the stomach, using a saturated solution through which carbonic acid has been passed. I have tried this in four or five cases, and have had the same effects as from injection.

Dr. J. H. Musser, of Philadelphia: I have used the gaseous injections to a certain extent; but my results have not been as marked as some which have been reported. My best results have been in two cases. One was a case of incipient phthisis, in which the patient gained thirteen and one-half pounds in four weeks. The second case has gained eight pounds in four weeks, and has much improved in general condition.

Dr. F. C. Shattuck, of Boston: I have used the sulphuretted hydrogen gas, and in several patients it produced collapse in varying degrees, with weak pulse, nausea, vomiting, and headache. In several other cases, although the treatment was well tolerated, it produced no good effect.

Dr. B. F. Westbrook, of Brooklyn, read a paper entitled

THE LOCAL TREATMENT OF DISEASES OF THE RESPIRATORY ORGANS.

In the treatment of phthisis the best results are obtained in the early stages of the disease, or where the disease, although further advanced, is limited to a small portion of the lung. The use of sprays is beneficial only in so far as we desire to treat the coexistent bronchitis, or cavities connected with bronchi of the second or third order. In incipient phthisis, with very little bronchial catarrh, local treatment is probably of little service. These cases are best treated with compressed air. In a large proportion of the cases we may hope to render the disease latent. The expansion of the lung favors the expectoration of the contents of the smaller tubes, and modifies the intra-thoracic circulation. The sittings should be frequent, every day or every second day. Ten minutes is usually sufficiently long for the patient to remain in the cabinet. The pressure should gradually be increased up to one-half or three-fourths of an inch. If used cautiously, this is the best method for the local treatment of incipient phthisis. With the Evans inhaler his results had also been satisfactory.

In the treatment of advanced cases of phthisis, the first effort must be to cure or diminish the bronchitis. The pneumatic treatment then comes into play. This gives better expansion, improves the circulation, and alters the action of the trophic nerves. In all cases internal medication has been combined with the local treatment. The more acute the disease, the higher the fever, and the more sudden the onset, the less can we expect to accomplish by treatment. In no case diagnosed as acute phthisis did treatment have the slightest effect.

The Association then adjourned.

THE CONNECTICUT STATE MEDICAL SOCIETY.

Ninety-sixth Annual Meeting, held in Hartford, May 25 and 26, 1887.

(Special Report for The Medical Record.)

Wednesday, May 25th—First Day—Morning Session.

The meeting was called to order in the County Court Room by The President, who then delivered the

ANNUAL ADDRESS.

The speaker reviewed briefly the work of the past year, and stated what was to come before the Society for action. He said there was no unfinished business to be brought up. A request had been sent to him and to the Secretary from the Fairfield County Medical Society, for a large representation from each county to the meeting of the fellows, but he thought that as the forty-nine incorporators were six years in formulating and procuring the charter, and as the snbject had been agitated many years ago, at which time the presidents of the county societies were made fellows *ex officio*, the State Society had a sufficiently large representation from each county.

A request had been received by the President and Secretary to have the Society contribute toward defraying the expenses of the Ninth International Medical Congress. He advised the members to contribute and endeavor to obtain a large membership.

The Wisconsin Medical Society had sent resolutions protesting against the immigration of the lame, halt, and blind paupers of other countries, and he suggested that a committee be appointed to take such action as was proper and report on these resolutions.

This suggestion was immediately followed, and it was voted to appoint such a committee.

The announcement of the various committees was then made.

The report of the Committee on

A LAW TO REGULATE THE PRACTICE OF MEDICINE

was then read. This committee had been appointed to consult with committees from the homœopathics and eclectics in regard to the enactment of a law prohibiting all from practising medicine and surgery except those who have diplomas from a recognized medical college and have had those diplomas registered with the clerk of the Superior Court. The committee reported that the bill had been introduced so late that it was crowded out by other business, and that the Judiciary Committee of the Legislature thought more time should be given to those who might object to such a law.

THE REPORT OF THE TREASURER

was then submitted. He reported a balance in the treasury of $759.12.

It was voted that all in arrears for two years be dropped from the roll of membership by the clerks of the several county societies.

A committee was appointed to solicit funds for the Ninth International Congress.

The Committee on Honorary Members presented the name of Dr. John C. Dalton, which, in accordance with the by-laws, was laid over for action at the next meeting. It was voted that a committee of two from each county

be elected by the county societies to revise the charter, and act, if advisable.

THE ELECTION OF OFFICERS

for the ensuing year was then held, with the following result:

President—Dr. Francis Bacon, of New Haven.

Vice-President—Dr. George L. Porter, of Bridgeport.

Treasurer—Dr. E. P. Swasey, of New Britain.

Secretary—Dr. S. B. St. John, of Hartford.

Committee on Matters of Professional Interest—Drs. F. E. Beckwith, of New Haven, and James Olmstead, of Middletown.

Dissertator—Dr. William H. Carmalt, of New Haven.

Delegates to American Medical Association—Drs. Lewis Barnes, Alfred North, W. L. Barber, C. J. Fox, T. M. Hills, A. L. Nelson, J. M. Kenniston, William Deming, M. C. O'Connor, and P. H. Ingalls.

Delegates were also appointed to attend the meetings of the State Societies of Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, New York, and New Jersey.

EVENING SESSION.

DR. W. E. CUSHING, of Boston, read a paper on

ULCERATION OF THE OS UTERI.

This was illustrated by micro-photographs shown by the stereopticon. The difference between simple ulceration and cancerous disease was very beautifully shown. The author spoke briefly on the treatment, giving a *résumé* of the most approved treatment, and also his own ideas in regard to astringents and the proper time to operate. He particularly emphasized the suggestion that in cancerous disease operation should be undertaken early.

Later in the evening the Society was tendered a reception by Dr. W. G. Russell at his residence on Farmington Avenue.

THURSDAY, MAY 26TH—SECOND DAY.

In the absence of both the President and Vice-President, the chair was occupied by Dr. R. L. Strickland. The Secretary reported that twenty-seven new members had been gained during the year. There had been eight deaths and seven removals. There was now a total membership of five hundred and eight.

Dr. T. M. Hills, of Willimantic, being detained at home by sickness, was unable to read his paper on

THE TOWN: ITS POOR AND THE PHYSICIAN'S LEGAL AND HUMANE RELATION TO THEM.

The paper was accordingly read by title.

Dr. W. H. Taylor, a delegate from the New Jersey Medical Society, was introduced, and this was followed by a report of the delegates of the State Society to other societies.

DR. A. E. ABRAMS then read a paper on

TREATMENT OF DISEASES OF THE EAR BY THE GENERAL PRACTITIONER.

He said that most general practitioners were unwilling or unable to treat diseases of the ear, and suggested that it was the duty of all to know how to treat these cases, as well as it was for them to understand the manner of handling pneumonia or dysentery. Difficult cases are sent to the specialist, and mild cases neglected. Thousands of cases of catarrhal deafness are allowed to go on without attention. Colds and throat-troubles leave the ear diseased, and we should always examine the ear before dismissing the patient.

DR. ST. JOHN said that while physicians thought little of ear-troubles and discharges, life insurance companies are particularly careful in such risks, and in some cases refuse to insure.

DR. A. W. NELSON reported that the Committee on County Resolves was in favor of a

REDUCTION IN THE SCALE OF CHARGES,

so that physicians might compete with unqualified practitioners and midwives, and by that means drive them from business, or else that schools should be established where at least the first principles of obstetrics could be taught. This, he thought, was a duty which the profession owed to the poor.

DR. GEORGE R. SHEPHERD reported several original cases of

CLIMACTERIC GLYCOSURIA.

He said that obstinate pruritus vulvæ was an unfailing symptom, and in all cases in which it occurred at about this period the urine should be examined. He called those cases climacteric where sugar appeared about the time of the change of life, and disappeared later without any special treatment. In his cases severe injuries caused no serious complications, as is usual in diabetes.

DR. J. B. KENT then read a paper on the

RELATION BETWEEN SCROFULA AND TUBERCLE.

His definition of scrofula was that it was a tubercle-forming process, and tubercle was only a more advanced stage of the same disease.

DR. T. H. RUSSELL read a paper on the

NEW REMEDIES — ANTIPYRINE, ANTIFEBRINE, PARALDEHYDE, AND COCAINE.

This paper was simply a *résumé* from the medical journals. Several papers were read by title. The meeting then adjourned at 2 P.M.

The annual banquet was held at the United States Hotel.

MASSACHUSETTS MEDICAL SOCIETY.

One Hundred and Sixth Annual Meeting, held in Boston, June 7 and 8, 1887.

TUESDAY, JUNE SEVENTH—FIRST DAY.

ON the morning of the first day the fellows visited the Massachusetts General, the City, and the Children's Hospitals, where they witnessed a number of interesting operations.

The first session was held in Huntington Hall, at 2 o'clock P.M.

DR. HERBERT L. BURRELL, of Boston, read a paper on

THE IMMEDIATE TREATMENT OF FRACTURE OF THE SPINE,

by rectification of the deformity and fixation by plaster of Paris. He showed two cases successfully treated by this method, and maintained that the measure was a rational one which should be employed in many cases. He insisted upon the immediate correction of the deformity, since softening of the cord from pressure may occur within forty-eight hours.

DR. STEPHEN W. DRIVER, of Cambridge, read a paper entitled

OBSERVATIONS ON THE PUERPERAL PELVIC LIGAMENTS.

The author had been able to detect flexion of the innominate bones upon the sacro-iliac joint, when the thigh was flexed on the tested side, in about seventy per cent. of some three hundred cases. The examination was made by placing the finger on the subpubic arch during flexion of the thigh, when the patient was walking or lying down.

DR. M. H. RICHARDSON, of Boston, presented a paper on

THE SURGICAL TREATMENT OF CHRONIC EMPYEMA,

which was read by title.

The following papers were also read: "Tumors of the Bladder," by Dr. G. W. Davis, of Holyoke; "Cases of

Burns, with Special Reference to Complications, Sequelæ, and Treatment," by Dr. J. E. Cleaves, of Medford; "The Relations of Tea Drinking to Disorders of the Nervous System," by Dr. W. N. Bullard, of Boston; "Pulmonary Tuberculosis as a Sequel to Ordinary Pleurisy with Effusion," by Dr. H. F. Vickery, of Boston; "Laparotomy for Pus in the Abdominal Cavity and for Peritonitis."

WEDNESDAY, JUNE 8TH—SECOND DAY.

DR. F. N. GOSS, Secretary, stated that 95 new members had been received since the last annual meeting, and 26 had died. There were now 1,661 names on the roll of membership.

DR. F. W. DRAPER, Treasurer, reported a balance of $2,315.21 in the treasury.

THE ELECTION OF OFFICERS

was then held, with the following result:

President—Dr. T. H. Gage, of Worcester.
Vice-President—Dr. W. G. Breck, of Springfield.
Corresponding Secretary—Dr. C. W. Swan, of Boston.
Recording Secretary—Dr. F. W. Goss, of Roxbury.
Treasurer—Dr. F. W. Draper, of Boston.
Librarian—Dr. E. W. Brigham, of Boston.
Orator—Dr. B. J. Jeffries, of Boston.
Annual Chairman—Dr. C. B. Porter, of Boston.

The following interesting papers were then read: "A Contribution to the Study of the Etiology of Summer Diarrhœa of Infants," by Dr. H. C. Haven, of Boston; "Sepsis and Antisepsis in Summer Diarrhœa," by Dr. S. A. Potter, of Roxbury; "Training Nurses," by Dr. A. Worcester, of Waltham; "The Value of Public Health Measures to the State," by Dr. S. W. Abbott, of Wakefield.

DR. GEORGE TOWNSEND, of Natick, then delivered

THE ANNUAL ORATION,

entitled "The Massachusetts Medical Society; its Relation to Medical Progress and to the Community in which we practise."

THE ANNUAL DINNER

was served in the Clarendon Street Rink, and was attended by upward of nine hundred of the fellows. Speeches were made by Dr. Gage, Governor Ames, Mr. G. M. Stearns, Rev. Brooke Herford, Col. Higginson, Dr. J. P. Reynolds, Mr. H. M. Shepard, and Mr. R. Wolcott.

WHITE BREAD *vs.* BROWN BREAD.—In a paper published in the *Quarterly Bulletin* of the New York Post-Graduate School, Dr. Geo. D. Hays says: "We have long been accustomed to hear that many of the evils of modern life owe their origin to our choice of *white* flour. That this is not so an examination of the wheat-berry will show. This has five coats—an epi-, meso-, and endocarp, an episperm, and a tegmen. The three outer ones have no value whatever as nutriment. Within the episperm is a layer of gluten-cells, chiefly albuminoids, and, finally, in the endosperm, which constitutes the bulk of the grain, we find starch mingled with albuminoid cells. In the old process of milling, the perisperm (the part within the episperm) was, on account of its close attachment to the inner husk, largely carried away, leaving the bolted flour the poorer for its loss. Hence the vegetarian, Sylvester Graham, whose name is applied to bread made from unbolted flour, was correct in his time in saying such bread contained the most nutriment. The present 'gradual reduction' process saves this portion of the wheat. The bran itself is composed of woody fibre, and contains absolutely no nutriment. It may have a mechanical value in those of a constipated tendency, but this is all. The wheat loaf and the white flour contain a much larger percentage of phosphates and gluten than the Graham loaf or unbolted flour."

Correspondence.

OUR BERLIN LETTER.

LEIPSIC AS A MEDICAL CENTRE—MEETING OF THE ANATOMICAL SOCIETY—PROFESSOR OLSHAUSEN—SCHROEDER'S MEDICAL WORK—THE SOCIETY OF GERMAN NATURALISTS AND PHYSICIANS—THE GERMAN PUBLIC HEALTH ASSOCIATION—DR. LIEBERKUHN—THE GERMAN SURGICAL CONGRESS.

May 1, 1887.

LEIPSIC is a medical centre of considerable interest. It may be rather more so to your correspondent than to your readers, for under the tuition of Cohnheim and Crede he spent a most pleasant and profitable semester here years ago. A visit here was in many respects pleasant, in others sad. Cohnheim has long since died. Weigert has removed to Frankfort, and Huber was absent from the city. Crede has laid down the reins to younger and stronger hands, being now seventy years of age and in poor health. He has been succeeded by Professor Zweifel, of Erlangen. Birch Hirschfeld is filling the place of the lamented Cohnheim to the satisfaction and edification of all. The University of Leipsic, medical department, had during the winter semester, 1887, 781 students.

The Anatomical Society, founded in Berlin in September last, held its session in the anatomical institute of the University of Leipsic recently. The meeting was, for so young a society, quite well attended, and interesting. The following papers among others were read: "The Asymmetry of the Face," by Dr. C. Hasse, of Breslau; "Observations on the Brain of Man," by Dr. M. v. Lenhosek, of Pesth; "The Mechanism of the Wrist-joint," by Professor Braune, of Leipsic; "The Development of the Pigment of the Skin, and the Nourishment of the Epidermis," by Dr. Karg, of Leipsic; "The Traces of Parietal Eyes in Man," by Professor Bardeleben, of Jena; "New Methods in the Field of Experimental Embryology," by Dr. Gerlach, of Erlangen. Interesting demonstrations in great numbers were made by different members. Professor A. v. Koelliker, of Wurtzburg, was president of the Society. The membership was 190, of which 78 were foreigners.

The most interesting part of the meeting, it can readily be conceived, was the social part. The evening before the first day a reception was given at the Russischer Hof. On the evening of the last day the members returned again to the same place for their banquet. Dr. Koelliker toasted Emperor Wilhelm and the Saxon royal family, also the rector magnificentissimus of the Leipsic University. Dr. His, of Leipsic, gave an account of the life and development of the new society *ab ovo*, and was followed by a number of other speakers who kept the guests roaring with laughter.

Professor Olshausen, of Halle, has been called to the chair in the Berlin University made vacant by the death of Schroeder. He made his first appearance before the students on the morning of May 5th. He made a very feeling address, speaking of his predecessor in the most tender terms. The first literary work of Schroeder showed unusual ability. It was a little brochure on "Hæmatoma Retrouterina." Schroeder was the first in Germany and the world to use prevention of infection in ovariotomy. Marion Sims thought we should treat the infection, Schroeder thought we should prevent it. These two had long discussions on this point. The speaker then dwelt at length on Schroeder's influence in the field of abdominal surgery. Especially was Schroeder most useful in the field of operations. He has to a great extent perfected that most dangerous of gynecological operations, myotomy. High amputation of the cervix, washing out of the carcinomatous cervix, and separation of the cervix from the body, is the work of Schroeder; also the wedge-shaped excision of the cervix in benign degeneration.

In total extirpation of the uterus he labored fruitfully. He thought that the cervix in pregnancy remained intact, and that the ring of contraction was not the internal os. He taught us much on the mode of action of expulsion in labor. Professor Olshausen spoke next of Schroeder's text-books, "Gynecology" and "Obstetrics." He complimented their accuracy and brevity. He spoke positively when he discussed a subject, and did not confuse the learner by theories and opinions. He spoke of him as a teacher, man, and physician. He loved his scholars, who filled his amphitheatre to the last place. Quiet consideration, quick conclusion, and firm treatment were Schroeder's. He treated fewer cases palliatively, but sought by means of operations to effect a radical cure.

Schroeder's memory was honored recently by a meeting in the University at the call of the Berlin Obstetrical and Gynecological Society. A large number of distinguished persons, medical and non-medical, were present. Among others were the widow and the nine children of the lamented gynecologist.

Professor Kaltenbach, of Giessen, succeeds Professor Olshausen as Professor of Obstetrics at Halle.

The sixtieth session of German Naturalists and Physicians will be held at Wiesbaden, September 18th to 24th next.

The German Association of Public Health will convene in Vienna, September 26th to October 28th, to meet with the International Hygienic and Demographic Congress. The latter will meet in the University building. All governments are requested to send delegates.

Dr. Nathaniel Lieberkuhn, Professor of Anatomy at the University of Marburg, and son of the discoverer of Lieberkuhn's glands, died recently at the age of sixty-five.

The sixteenth session of the German Congress of Physicians was held in Berlin in April. Professor Volkmann, of Halle, was president, and Dr. Guilt, of Berlin, was secretary. Professor v. Bergmann, of Berlin, was elected president for next year. The session was of great interest, but a full report is impossible here. The following are a few selections from the mass of matter presented:

Dr. Sonneberg, of Berlin, read on the subject of Arthropathia Tabidorum. From an anatomical standpoint, he urged the fact that in all cases of disease of the joints existing with tabes there is present, in a greater or less degree, arthritis deformans. It is distinguished from the usual arthritis deformans only through a more rapid course and increase of action. Otherwise the characteristic symptoms of tabes are present. A much more extensive exudation into the joint is found, and while the dislocation in arthritis deformans is progressive in character, the arthropathia tabidorum is oftener retrogressive. Luxations occur just as often from retrocapsular osteophytes projecting from the periosteum. In reference to the casual connection of the affections of the joints with the tabes, the author thought the theory recently promulgated by Charcot, that the fractures and disease of the joints were to be referred to purulent collection, was the true one. This opinion has recently received anatomical support. Recent investigators, as Oppenheim and others, have found a degeneration of peripheral nerves. Through this the connection between disease of the joints and tabes is brought a little closer and answered in a positive manner. Therapeutically, expectant treatment is mostly to be followed.

Professor Volkmann, of Halle, raised the question whether single collections, which have been frequently observed recently in those suffering from tabes, are not preceded by syphilis; for surely syphilis predisposes the origin of tabes.

Dr. Rotter, of Berlin, demonstrated a number of preparations from patients which had suffered from neuropathic joint affections and the most varied forms of tabes, and spoke briefly concerning them.

Dr Kroenig, of Berlin, has observed three cases of tabes in which the spinal column was peculiarly deformed and showed spondylisthesis. Therapeutically, the use of corsets made of whalebone after Beely's plan were of much benefit.

Dr. Koegel, of Halle, had observed seven cases of tabes. In only two of these did deformity of the bone occur to any degree. This, however, disappeared under the proper treatment. He spoke of the influence of traumatism in the causation. The local cause of joint affections spoken of by Virchow is often found present. A traumatic influence acts on the part, and, on account of the spinal cord being diseased, infects the substance. Not only rupture of the bones but also of the capsule can occur. The infrequent occurrence of rupture of the tendons is proved by the trophic disturbance of the fibrous places.

For the origin of fractures of the joints we infer the presence of an unusual fragility of the bones; however, this is not necessarily always present. In the cases of fracture of the joints which he had treated, the contrary was the case, the bones being quite hard. Perhaps the bulging in of the masses of connective tissue is the primary cause of the fracture.

Professor Volkmann said there were two kinds of bone-fragility. One is found in thinned bones, the other in quite strong bones. In the latter, healing follows promptly. The only explanation of a failure to unite is the disturbance of organic bone-substance.

"The Operative Treatment of Urethral and Vesical Fistula" was the subject of a paper by Professor Woelfler, of Gratz, who said that in the removal of the defects of the urethra and bladder we have made decided advances. We however have reached a limit. Our inability to obtain success is often caused by the fact that the defects are too large to permit of the borders being brought together. This is true in the case of the bladder as well as of the urethra. Another reason of difficulty in attaining our aim is the fact that not enough mucous membrane is present to suffice. The author wished therefore to present a plan of operating which would answer in case of necessity in place of the typical operation. He divided the fistulæ into cicatricial and purulent. When we find defects of the urethra present, we suppose that the canal is permeable. In one case of Woelfler's, however, there was a cicatricial traumatic urethral fistula which presented the exact condition of a rectal fistula. There was a dilatation of the part leading to the fistula, and the part leading from it was obliterated. It was found necessary to make a section of the constricted part, which was done, and fifteen peri-urethral sutures were passed, besides numerous small sutures of the mucous membrane. The result was entirely satisfactory and no stricture occurred in consequence. This kind of an operation is the type for the kind of cases first named. The second group consists of those fistulæ which are present from phlegmonous processes and infiltration of the urine. In these cases the borders should be cut loose and peri-urethral sutures should be then applied.

Dr. Woelfler also reported his experience in the effect of ligature of the thyroid artery in goitre. We must think first of the anatomical connection of artery when we wish to induce shrinkage of a goitre by the ligature of the arteries which lead to the thyroid gland. Ligature of the superior thyroid in dogs does not cause advancing gangrene, but necrotic processes form and complete destruction of the tissue without that of the capsule. Woelfler's first ligature of this artery in man was in the case of a woman aged forty-five, in whom it was done in consequence of an error of diagnosis. The patient came to the clinic with a high grade of dyspnœa, and said that the goitre which was present had been of the same size for years. The reporter thought he had to deal with a benign condition, which, however, later proved to be carcinoma. The ligation was smoothly done, the recovery was without a bad symptom, and the patient left the institution in four weeks. The dyspnœa was gone and the circumference of the neck was less. In four weeks, however, the difficult breathing returned and the patient

came again to the hospital, where a little later she died. On post-mortem examination the author found that the right half of the thyroid gland was notably diminished in size in consequence of a necrobiotic process. He was convinced that the arteries at the place of ligature were obliterated and that peripherally they were callous. This condition of necrobiosis proved that the difficult breathing, in consequence of collapsed goitre, disappeared immediately, but on the other hand the dwindling of the goitre went on very slowly. The manner in which the necrosis completed itself was shown by the reporter, upon a patient in whom he had ligated only the right superior and inferior thyroid arteries. The difficult breathing disappeared immediately. The circumference of the neck lessened only gradually, but was reduced from 44 to 38 centimetres. The reporter feared that a compensatory hypertrophy of the left side would take place. The opposite however occurred. Not only the isthmus, but also the left half of the thyroid gland, shrunk. In malignant goitre one should not undertake to ligate, because the compensatory circulation is not sufficient. In struma, however, total extirpation by the ligature of the superior and inferior thyroid artery can be compensated.

"The Action of Iodoform" was the subject of an article by Dr. De Ruyter, of Berlin.

Dr. v. Tischendorf, of Leipsic, reported a case of enterostomy for congenital atresia of the ileum. He presented the specimen, which had been brought to him on the sixth day of life for treatment. The doctor thought he had a case of atresia of the colon to treat, as this is sometimes congenital. Laparotomy showed an atresia of the ileum, 25 ctm. above the cæcum. The child lived only fourteen days after the operation. It did not vomit any more, but died from general weakness.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MEDICAL COUNCIL AND THE SOCIETY OF APOTHECARIES—SIR WILLIAM GULL ON THE VALUE OF DRUGS—INTESTINAL SURGERY—THE FREQUENCY OF TUBAL DISEASE.

LONDON, May 13, 1887.

THE Medical Council met again on Tuesday last, for the third time within twice as many months. Although some other business has to be disposed of, the chief subject for consideration, and that for which the Council has really been summoned now, is the question of the Society of Apothecaries. Are they to be snuffed out, or is the Council to accord them recognition and erect them into an independent examining body by appointing surgical examiners, as the Society now asks them to do? Such examiners already exist, but they have not been appointed by the Council under the new act, and are not, therefore, officially recognized. There can be little doubt that the Council will comply with the request made to them. Such, at any rate, is the natural conclusion to be drawn from the defeat yesterday of Dr. Struthers' amendment by nineteen to nine votes. The discussion had lasted three days. It was dry enough in conscience, and was rendered still more so by the amount of legal matter some of the speakers thought fit to interpolate. A few incidents relieved the dry monotony of the proceedings. Dr. Struthers denounced the Apothecaries' Society as a mere trading corporation, and excited some risibility in his audience by describing a visit he had lately paid to the retail department. He proceeded to exhibit a bottle of tincture, some pills, and a bottle of eau-de-cologne which he had purchased. Sir Walter Foster (with an obvious desire to pose to advantage before his constituents) said that he was glad that Dr. Struthers had introduced something in the shape of bottles that recalled to their minds the humbler branches of the profession, which were doing good and useful work in the community. Sir William Gull returned to the trade question at a later stage of the debate, and took the opportunity to decry the treatment of disease by drugs. When the Prince of Wales was ill of typhoid fever, how many doses of drugs, he asked, did the prince take? Of course, any other patient would have done as an illustration, but Sir William Gull would thereby have missed his opportunity of reminding his auditory that *he* was the physician in charge of the Prince of Wales on that occasion. He concluded his speech by remarking that, whatever might be said of general practitioners (and he had evidently nothing good to say of them), there was one universal practitioner better than all of them when you were sick, viz., a warm bed (with, of course, Sir William Gull sitting at the bedside to see to the gruel and beef-tea, and to prevent any low-bred general practitioner from doing such an improper thing as give a dose of medicine).

The last meeting of the Medical and Chirurgical Society was devoted to intestinal surgery. Mr. Barker opened the ball by narrating a case on which he had operated with success, in University College Hospital. A married woman, aged twenty-eight, came under treatment for chronic bowel trouble. For sixteen months before admission she had passed blood with the motions, and during the latter half of this time had been conscious of the presence of a foreign body in her rectum. On making an examination, an intussusception of the rectum of about three inches in length was found, and surrounding the apex of the intussuscepted portion a mass of new-growth. The latter infiltrated the coats of the intestine, and was judged to be malignant. The intussusception could not be reduced, and Mr. Barker therefore determined to remove it along with the new-growth. The intussusception having been drawn down, the left index-finger was passed well into the intussusception, and the two layers of bowel, whose peritoneal coats were opposed, were pinched together beyond the growth between the finger and thumb. They were then stitched together by interrupted sutures. When the entire circumference of the bowel had thus been encircled with a row of stitches above the growth, a second row was similarly introduced about half an inch higher up. The whole mass was then cut away between the two rows of stitches. Only one small vessel bled, and was tied. The growth was found to be a mass of adenoid epithelioma with a margin of healthy tissue above it. The patient's recovery was rapid and uninterrupted, and she remained well a year after the operation. Mr. Barker referred to the rarity of intussusception of the lower bowel, produced by malignant growths, and said he had only been able to collect eleven cases. Six of these were either purely rectal or in the sigmoid flexure. Of this number, four were operated on; but two of these (cases of Professor Verneuil) died. Of the remaining two, one was operated on by Kulenkampoff, with an ultimately good result, though a loop of small intestine was opened in performing the operation, and a provisional colotomy had to be done. The fourth case was his own, and made the second successful one on record.

A paper by Mr. Stanmore Bishop was then read, in which were detailed the results of some experiments which he had performed on animals for the purpose of determining the best form of suture to unite the divided ends of the bowel after excision of small portions of the small intestine. He preferred one which he had himself devised. As in Lembert's suture, the serous surfaces of the intestinal wall were inverted and kept in contact by the sutures, but the latter were continuous and were passed from the inside. The knots, also, were so arranged that they fell into the lumen of the bowel instead of into the abdominal cavity. Mr. Croft defended Lembert's method, and remarked that, as thousands of sutures had fallen into the abdominal cavity without any bad result, he did not think it very important to prevent it. Mr. Treves remarked that he had himself experimented on the intestines of dogs by many methods, and had finally fallen

back on Lembert's as the best. He protested against drawing conclusions from experiments made on dogs. A clumsy stitch of any kind would succeed in uniting a dog's intestine. Mr. Knowsley Thornton objected to Mr. Stanmore Bishop's method; that the passing the sutures from the inside of the bowel to the outside might allow septic matter to pass into the peritoneum. The continuity of the suture, also, might lead to sloughing. Sir Spencer Wells commended Mr. Stanmore Bishop's plan, but it was quite clear that in the opinion of the majority of the speakers Lembert's suture still deserved to hold the first place.

Diseases of the Fallopian tubes have hitherto been considered rather infrequent, and many have not been slow to hint at exaggeration on the part of observers who profess to encounter them with tolerable frequency. Mr. Lawson Tait, in particular, has been for years about as much abused as it is possible for a man to be. Clinical observations are naturally open to fallacies, but those made on the dead body are incontrovertible. The matter has recently been tested in this manner by Dr. Lewers, Assistant Obstetric Physician to the London Hospital, and he has found evidence of tubal disease (restricting the expression to hydrosalpinx, pyosalpinx, and hæmatosalpinx) in seventeen cases out of one hundred bodies of women dying in the London Hospital from various diseases. The cases were not selected, but consecutive, and no one of these seventeen cases came from the obstetric wards, though some of the one hundred cases examined did. This is a sufficiently startling conclusion, and points to a much greater frequency of these diseases than either clinical or pathological observers have hitherto supposed.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 5 to June 11, 1887.

FRYER, B. E., Major and Surgeon. Granted sick leave for one month. S. O. 28, current series, Division of the Pacific, amended by S. O. 29, Division of the Pacific, June 2, 1887.

TREMAINE, W. S., Major and Surgeon. Sick leave still further extended two months on account of sickness. S. O. 129, A. G. O., June 6, 1887.

APPEL, A. H., Captain and Assistant Surgeon. Granted six months' leave of absence on surgeon's certificate of disability. S. O. 127, A. G. O., June 3, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending June 11, 1887.

VAN REYPEN, W. K., Surgeon. Ordered, June 8th, for examination preliminary to promotion as Medical Inspector.

ROBINSON, SOMERSET, Medical Inspector. Ordered, June 20th, before a Retiring Board, convened at Mare Island, Cal.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 11, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	1
Scarlet fever	50	8
Cerebro-spinal meningitis	10	9
Measles	39	5
Diphtheria	104	45
Small-pox	8	2
Yellow fever	0	0

Society Items.

AMERICAN MEDICAL ASSOCIATION.

THE following are added to our telegraphic report last week:

The *Medical Standard* (Chicago) and the *Chicago Medical Journal and Examiner* published very acceptable daily editions during the meeting of the American Medical Association. The former was under the lively reportorial and editorial management of Dr. J. R. Gray, and the latter had the highly commendable feature of being published without the aid of advertisements.

Dr. Ely Van de Warker, of Syracuse, N. Y., was elected Chairman of the Section on Obstetrics and Diseases of Women, and Dr. E. W. Cushing, of Boston, Secretary.

The following eminent gentlemen were elected on the last day of the Convention, in conformity with the new by-law, to deliver addresses in the general sessions of the next annual meeting:

Address on General Medicine, Beverly Cole, M.D., of San Francisco.

Address on Surgery, E. M. Moore, M.D., of Rochester, N. Y.

Address on State Medicine, Jas. L. Cabell, M.D., of Virginia.

Drs. J. M. Toner, of Washington; E. Grissom, of Raleigh, N. C.; and D. Colvin, of Clyde, N. Y., were appointed a committee to inform these gentlemen of their election, and to fill vacancies in case of either death or declination.

On resolution offered by Dr. J. B. Hamilton, Surgeon-General Marine Hospital Service, and supported by Dr. G. H. Rohe, of Baltimore, the resolution introduced by Dr. J. McF. Gaston, of Atlanta, providing for a committee to ask President Cleveland to appoint two additional members on the committee sent out by the Government to investigate the subject of yellow-fever inoculation, was rescinded.

Committee on the Criminality of Fœticide: Drs. I. N. Quimby, of Jersey City; W. B. Atkinson, of Philadelphia, and W. H. Byford, of Chicago.

Committee on Coroners: Dr. H. O. Marcy, of Boston; J. H. Burge, of Brooklyn, and W. W. Dawson, of Cincinnati.

Committee on Immigration Sanitation: Drs. A. N. Bell, of New York; H. A. Johnson, of Illinois, and J. H. Kellogg, of Michigan.

The address on Surgery, by Dr. Mudd, of St. Louis, who was unavoidably absent on account of sickness in his family, was referred to the Committee on Publication. Dr. Scott, of Cleveland, was prevented from preparing the address on Ophthalmology and Otology on account of the death of his wife.

Dr. N. S. Davis' resolution on graduates of dental and oral schools or colleges being recognized as members of the regular profession of medicine, and also his resolution concerning the annual dinner of the Association, were adopted.

Committee on Dietetics: Drs. A. E. Wood and Frank Woodbury, of Pennsylvania, and Frank H. Whittemore, of Connecticut.

Committee on Uniformity of Medical Legislation: Drs. P. H. Millard, of Minnesota; H. A. Johnson, of Illinois; R. H. Plummer, of California; C. B. Belt, of Massachusetts; and C. W. Dulles, of Pennsylvania.

The member of the Judicial Council is Benjamin McCluer, instead of A. W. McCluer, of Iowa.

The Secretary of the Section on Ophthalmology is Dr. Edward Jackson, of Philadelphia.

The register contained nearly twelve hundred and fifty names.

DANGERS AND ACCIDENTS OF INTUBATION.

BY DILLON BROWN, M.D.,
NEW YORK.

THE accidents of intubation of the larynx are many, but the *unavoidable* accidents are few, and, with the exception of pushing down pseudo-membrane before the tube —which is a rare complication—they are not important. I shall discuss, *first*, those accidents which can be and should be avoided, due to lack of skill, carelessness, or imperfect instruments, and *second*, the unavoidable accidents, and *last*, some of the dangers of intubation, theoretical and practical.

Avoidable accidents.—1. Asphyxia from prolonged attempts at introduction.

2. False passages made in attempts at introduction.

3. Asphyxia from slow accumulation of secretions in the tube.

4. Slipping of tube into the trachea.

5. Asphyxia from swelling over the head of the tube.

6. Passing the tube into the œsophagus.

7. Injuries to the larynx in attempts at removal.

8. Miscellaneous.

Unavoidable accidents.—9. Pushing down pseudo-membrane before the tube.

10. Fatal obstruction from fragments of membrane in or below the tube.

11. Coughing out of the tube.

Dangers, theoretical and practical.—12. Shock of the operation.

13. Inspired air being septic and causing pneumonia.

14. Food and liquids entering the bronchi.

15. Ulcerations due to the pressure of the tube.

16. Œdema, from various causes.

17. Dangers from applications by means of the tube.

Asphyxia from prolonged attempts at introduction.—The tube, in most cases, should be inserted into the larynx quickly, and on the first trial. Every additional attempt and every prolonged one is harmful; but there is less injury done by several short trials at introduction than by a single prolonged one, even if successful.

False passages made in attempts at introduction.—In cases of acute stenosis the tube slips easily into the larynx, and it requires no more force to push it well into position than it does to pass a sound through the healthy urethra. In the two cases which have come under my notice of false passages made in attempts at introduction, an unjustifiable amount of force was used to push the tube in place. In both of these, its insertion caused a complete cessation of respiration, which was supposed to be due to the pushing down before it of membrane. The autopsies, however, showed that in the first case the tube had entered one of the ventricles of the larynx, and was forced down through the surrounding tissues along the outside of the trachea. In the second case there was a rupture through the wall which separates the œsophagus and the trachea, and respiration was prevented by the pressure of the tube against this yielding membranous division.

Asphyxia from the slow accumulation of secretions in the tube.—In a certain proportion of cases, especially in those in which the patient is weak and coughs but seldom, and in which the amount of secretion is small, the tube gradually becomes lined, sufficiently to cause obstruction, with a mixture of what seems to be mucus and pus. Although this is not a common complication, and can be prevented to a great extent by the faithful use of the steam atomizer, it is well to be on our guard against it, and in all cases of secondary dyspnœa to remove the tube, and make sure that it contains no obstruction.

Slipping of the tube into the trachea.—This is an accident which, I believe, has never happened, and which, I believe, never can happen when a proper-sized tube is used, except as a result of injuries to the larynx made in attempts at removal. If the extractor is passed into the larynx, but outside of the tube, and is forcibly withdrawn with its blades widely open, great damage will be done to the larynx. It is possible in this manner to split open the cricoid cartilage, and so enlarge the opening of the glottis as to allow the head of a tube to slip through the larynx into the trachea. This is an accident which can always be avoided.

The occurrence of this accident has been reported three times, but it seems to me that a careful analysis of these reports will show that such has not been the case. It should be remembered that the head of the tube, even if pushed below both the ventricular bands and the true cords, will still remain in the larynx, being held by its narrow, sub-glottic division. Again, as the head of the tube is smaller than the calibre of the trachea, it would fall by its own weight until its lower end was arrested at the bifurcation or became lodged in a bronchus. Therefore, if this accident should happen, the tube could not be felt by the finger, and neither could it be grasped and removed by the extractor in the usual manner. In Dr. Waxham's case, after anæsthetizing the child, the tube was grasped by the extractor and removed without force in the usual way. He bases his diagnosis on the presence of a croupy cough and the ability to swallow easily. These symptoms would also appear if the head were retained in the sub-glottic division of the larynx. In Dr. Eichberg's first case an old-fashioned, small-headed tube was used, and it was pushed down in attempts at removal. Although the case is not reported minutely enough to state positively whether the head was in the sub-glottic division of the larynx or in the trachea, it seems to me that the evidence would indicate the former place rather than the latter as its position. The diagnosis of its position was apparently based upon the fact that it had been pushed below the true cords, the retaining power of the sub-glottic portion of the larynx being ignored. After this an unsuccessful attempt was made to remove it, from which I inferred that it could be felt by the extractor. Again, the child's breathing was perfectly easy, and upon opening the trachea the head of the tube was found above this opening. In Dr. Eichberg's second case the tube, also one of the early ones, slipped through the chink of the glottis, and was therefore supposed to be in the trachea. Of the three cases reported, in one of them the head of the tube was not in the trachea; and in the other two, an old-fashioned, small-headed tube was used, and its position in the trachea was not demonstrated. When there is much swelling over the head of the tube, it may be erroneously supposed to have slipped below the cords.

Asphyxia from swelling over the head of the tube.—This is a complication easily overcome by inserting a tube

with a larger head. It has occurred in two of my cases, and in the first one I did not recognize the cause of the secondary dyspnœa until the autopsy, after the child had died from asphyxia. It is a good plan, before removing the tube in cases of secondary dyspnœa, to exclude this accident, as its cause, by a digital examination of the larynx.

Passing the tube into the œsophagus.—There should be no difficulty in determining whether the tube is in the larynx or in the œsophagus, although this mistake has been made in two cases which have come under my notice; and in both of them the child died from asphyxia. After coughing up the tube, it has been swallowed several times, and in attempts at introduction it has been lost in the stomach a number of times. In all these cases its presence caused no trouble, and if the patient recovered, it was passed per rectum without difficulty. In one case, where it was thought to have been swallowed, it was unexpectedly expelled from the larynx several days later, and in another case it was found in the pocket of one of the other children.

Injuries to the larynx in attempts at removal.—In removing the tube no force is required; and in cases in which the extractor comes away with difficulty, it is because it is caught in the tissues of the larynx, and much injury will be done if it is forcibly removed with the blades widely open. Not only will you lacerate the larynx, but may even split open the cricoid cartilage, and so enlarge the chink of the glottis that on the next attempt to remove it you will push it into the trachea. This accident has happened in practice on the cadaver.

Miscellaneous.—At times, after the removal of the tube, there occurs a spasm of the glottis from the irritation of the inspired air upon the larynx, which has been protected so long. This can be avoided to a great degree by giving an opiate just before its removal, but it is always advisable, before removing the tube, to have everything prepared for its immediate reinsertion, if necessary. This rapid return of the dyspnœa may also be due to a diphtheritic paralysis of the abductors or to an œdema of the glottis. The string should be of strong braided silk, not only to prevent its breaking, but to prevent the more serious complication of its untwisting and catching in the eye of the tube, so that it cannot be withdrawn without removing the tube. The string should be cut as short as possible and withdrawn slowly to prevent its cutting the surrounding tissues. The lacerations made by the gag, and by the finger in locating the larynx, are unimportant.

Pushing down pseudo-membrane before the tube.—This is the gravest accident which the operator can encounter, but fortunately it is an extremely rare one. On the first introduction of the tube, sufficient membrane has been pushed down to cause asphyxia in only one of Dr. O'Dwyer's cases, and in two of my own. In each case, after withdrawing the tube, the obstruction was expelled and the dyspnœa relieved. Later, when the membrane has become more or less detached and broken down, upon the reintroduction of the tube, the liability to this accident is increased. In connection with this danger, one point regarding the introduction of the tube must be closely observed. The tube should be pushed well down in position, and held down by the finger while the obturator is being removed. Otherwise, when it is pushed into position after the removal of the obturator, the lower end is unprotected, and can easily strip off enough membrane to cause obstruction at that point. Upon the reintroduction of the tube I have pushed down sufficient membrane to cause obstruction in four cases, but in only one of these was it a fatal obstruction. This occurred eighteen days after the first intubation, and shows how long the membrane will sometimes persist.

Other accidents, and those avoidable ones, may be mistaken for this—*e.g.*, apnœa from prolonged attempts at introduction, pushing the tube through a ventricle of the larynx, and other false passages, etc.

Fatal obstruction from fragments of membrane in or below the tube.—This is also a rare accident, and it has not occurred in any of my cases. If the tube becomes obstructed, it will usually be expelled, and it is on this account that it is advisable to have it retained in the larynx as loosely as possible. Certainly, the number of deaths from clogging of the tube after intubation, as shown in the reported cases, compares in a remarkably favorable manner with the number of deaths from the same cause after tracheotomy.

Coughing out of the tube.—This is undoubtedly a source of danger, but it can be entirely obviated by making the retaining swell of the tube sufficiently large. It is intended by Dr. O'Dwyer that the tubes be held loosely in the larynx, so that when they are no longer needed, or become obstructed, they will be expelled. After being coughed out, if the dyspnœa does return, it is usually several hours before it becomes extreme, and there is time to reach the patient and reinsert the tube. In my own practice I have had one death from laryngeal obstruction after coughing out of the tube. It was a boy fourteen months old. I removed the tube on the fifth day, but was compelled to reinsert it the next day. From this time the tube was frequently expelled, being retained from five to sixteen hours. I had a special tube made with a very large retaining swell, but it was apparently expelled as easily as the others. There was paralysis of the pharyngeal muscles, and of the external rectus of the eye, and it seems to me that the cause of the frequent expulsion was a paralysis of the muscles of the larynx. There was usually time to reach the child and reinsert the tube; but on the twenty-eighth day it was some time after the expulsion of the tube before I was sent for, and when I reached the patient two and one-half hours after it was coughed out, he was dead. I obtained the larynx, and there were no macroscopical appearances to account for the return of the obstruction.

Shock of the operation.—This is very slight when the operation is done quickly and skilfully. In a certain number of cases of laryngeal diphtheria, soon after intubation, the temperature begins to rise, and the condition of the patient rapidly grows worse. However, this occurs just as frequently after tracheotomy, and it does not occur after intubation of the larynx for stenosis due to other causes—*e.g.*, syphilitic stenosis or catarrhal croup. Therefore, it seems to me that this change is not due to the operation itself, but is the result of relieving the laryngeal obstruction, this acting in some manner as an antipyretic. We know that nitrogen acts as an antipyretic, and may not its action be due to its cutting off the supply of oxygen rather than to any effect of its own?

Inspired air being septic and causing pneumonia, and *food and liquids entering the bronchi.*—My experience has been that the cause of death, when due to pulmonary complications, is, in the vast majority of cases, not pneumonia, but an extension of the disease to the bronchi—a diphtheritic bronchitis. Again, pneumonia is not a common complication of diphtheria when the larynx is not involved, although the same condition exists—the inspired air is septic. If the extension of the disease could be caused by this contaminated air, we would expect laryngeal or bronchial diphtheria to occur oftener, for in not one case of diphtheria out of ten is the larynx or the bronchi involved.

In no autopsy at the New York Foundling Asylum has food ever been found in the bronchi, and I believe that this is a theoretical danger rather than a real one.

Ulcerations due to the pressure of the tube.—That ulceration may originate in this way is without question, but this will be fully discussed in the paper on the pathology of the larynx after intubation. In none of the cases reported has the presence of the tube caused any harm. Certainly the tracheotomy tube does do injury, and it is not very rare to see cases of retained tracheal tubes due to granulations, incurvation of the wound, etc.,

and occasionally also death from hemorrhage following ulceration through a blood-vessel.

Œdema of the larynx; local applications.—In cases of laryngeal diphtheria the stenosis is due not so much to the pseudo-membrane as to the swelling of the tissues beneath it. The pressure of the tube diminishes this swelling in a marked degree, besides hastening the disappearance of the membrane, if not even preventing its formation. This can be demonstrated at nearly every autopsy on cases dying after intubation. In making local applications by coating the tube with strong astringents, it is possible to cause an œdema of the glottis, which takes a long time to disappear. I lost one case from this cause, due to the too enthusiastic application of an ointment of nitrate of silver—3 ij. to ℥ j.—just after reviewing the works of Dr. Horace Green. An application made in this manner is not one of short duration, but extends over several hours, or even days. Lacerations made in attempts at insertion or removal may set up an œdema.

102 East Fifty-seventh Street.

TRACHEOTOMY FOLLOWING INTUBATION OF THE LARYNX.[1]

By IRWIN H. HANCE, M.D.,

Resident Physician Nursery and Child's Hospital, New York.

My object in writing this paper is to report in detail a case where tracheotomy was performed after the tube had failed to give relief in a child suffering from membranous croup and scarlatina.

The following is a history of the case: Alfred J——, aged twenty months. Father English; mother Irish. Admitted to the hospital October 16, 1886. Nursed for eighteen months. Has had measles. Is well nourished, but pale. No glandular enlargement.

October 22d.—Appeared sick during day. Throat red. Slight elevation of temperature.

October 23d.—Well-marked diphtheritic patches on the tonsils.

October 24th.—In the morning was a little croupy; continued with croupy cough during the day, and was vomited three times, the symptoms thus being relieved. Child has developed a well-marked scarlatinous eruption.

October 25th.—At 10.30 A.M. child was much worse, there being well-marked dyspnœa, with recession of chest-walls, cyanosis, and other signs of laryngeal stenosis. At 10.45 a tube was introduced (No. 2), and almost immediately coughed out, along with much thick mucus; operation was again repeated with a like result. When the tube was introduced for the third time it became obstructed, and caused a serious embarrassment of breathing. It was removed at once, and there was almost complete cessation of respiration, but artificial respiration revived the child in a few minutes.

Dr. Wheelock, the attending physician, then advised that laryngotomy should be performed if the next introduction of the tube failed to give relief. At 11.30 A.M tube was reintroduced. At the end of ten minutes it was removed, and was found to be plugged with such thick mucus that almost a cast of the tube was formed. Cleansed and once more inserted; this time the respirations improved for a short time.

At 12.10 P.M. respirations worse, tube coughed up. Rapid incision was made through the crico-thyroid membrane and the cricoid cartilage, affording the child immediate relief. Wound was held open by retractors and the trachea thoroughly cleansed from mucus. Small hard rubber tracheal tube introduced. From this time on there was not the least return of any dyspnœa.

At 7 P.M. child was quietly sleeping, breathing without any apparent effort. No cyanosis existed, and the scarlatinous eruption had entirely returned. Was able to take liquid food. Temperature during the night reached 106⅘° F. Failed slowly and died at 8 A.M., October 26th, from the systemic poisoning of the two diseases.

Necropsy was held twenty-six hours after death by the pathologist, Dr. N. H. Henry. Rigor mortis absent. Marked post-mortem ecchymosis. An incision passes through crico-thyroid membrane and cricoid cartilage; edges of wound are in a fair condition. Trachea shows an abundant fibrinous exudation, which is easily lifted from the surface. Lungs: Slight hypostatic congestion. Pericardium: Increase in the amount of pericardial fluid. Heart: Valves normal; muscular tissue pale. Liver and spleen congested. Kidneys somewhat enlarged. Increased amount of cortical substance. Medullary portion very pale. Capsules easily separated. Brain not examined.

In reviewing the history of this case I may emphasize the statement that the tubes were given a thorough trial and proved utterly useless. Now, what was the cause of this failure on the part of the tube to relieve the child's symptoms? It seems to me that two things conjoined to bring about this result, viz., an excess of thick, tenacious mucus in the trachea and a partial dislodgement of the false membrane by the introduction of the tube. The former was present to a marked degree, and we may safely assert that some membrane was dislodged, because on one occasion after the withdrawal of the tube, artificial respiration was required to restore the child's function of breathing. Was the operation of tracheotomy deferred longer than was necessary? At present, in view of my experience with this case, I think that on another like occasion I should resort to tracheotomy earlier, because many attempts at the introduction of a tube unquestionably cause a more or less decided depression of the child. The selection of the crico-thyroid membrane as the best place to incise the trachea was decided upon because of the ease and rapidity with which the operation could then be performed, one rapid incision being all that was required.

Would the child's chances of recovery have been better if tracheotomy had been performed at first without using the tubes?

This is an extremely difficult question to answer; I can only say that tracheotomy in children under two years of age terminates fatally in a very large percentage of cases, and that intubation gives a fair showing. From my own experience I feel that intubation in such young children gives equally as good results as tracheotomy.

Thus far I have considered only my own case; I ask your attention now to a few other cases which have been reported in the medical papers.

Dr. Ferguson,[1] of Troy, reports a case similar to mine, in which the tube detached a piece of membrane. Tracheotomy was performed; the result was a complete relief to the dyspnœa, although the child died in thirty hours.

Dr. Montgomery,[2] of Philadelphia, did tracheotomy because he was unable to reach the tube with the retractor. He thought that the tube, which, he states, was of small size for the child, had been forced below the vocal cords; it, however, had been coughed up and swallowed, being passed per rectum two days later. This child recovered. Dr. J. Eichberg, of Cincinnati, reports[3] two cases where he had to tracheotomize the child in order to recover the tube:

Case 1, aged seven. After the tube had been in the larynx for six days, he found that it had fallen "by its own weight" down so far as to require tracheotomy in order to remove it; the wound was made through the cricoid cartilage, and he tried to get primary union, but failed, but was obliged afterward to introduce a tracheal tube. Result, recovery.

Case 2, aged three. Five days after its introduction

[1] Read before the New York Academy of Medicine, June 2, 1887.

[1] New York Medical Journal, March 5, 1887, vol. 45, No. 10, p. 273.
[2] The Medical News, March 5, 1887, vol. 50, No. 10.
[3] Lancet-Clinic of Cincinnati, vol. 18, Nos. 4 and 11, pages 97 and 321.

he sought to remove the tube, but failed, because the instrument, which was an old extractor, slipped, and, in his attempts at removal, he forced the tube into the trachea. By operating he recovered the tube, and the child made a good recovery. Here again he tried to get primary union, but failed, having to resort later to the use of the tracheal tube.

Dr. H. H. Mudel, of St. Louis, seems to have been very unfortunate in his experience of the use of intubation. He reports[1] six cases, in three of which he was obliged to resort to tracheotomy. His notes are scanty, and are as follows:

Case 1, seven years of age. Came near suffocating from loose membrane. Tracheotomy. No result noted.

Case 2, four years of age. Had had intubation tube in for four days. Tracheotomy because there was an excess of secretion, and child was unable to swallow. Result: three weeks have elapsed since the operation, and he thinks child will recover.

Case 3, three to four years of age. Tracheotomy because tube could not be retained. Result: recovery.

Dr. Dillon Brown, of New York, reports one case: Child between one and two years of age. Tube failed to give relief. Cause was supposed to be due to loose membrane. Tracheotomy tube was introduced, but this failed to relieve the child's symptoms, death occurring on the table. Autopsy revealed the probable cause of failure, as the membrane extended down to the third and fourth division of the bronchi.

Thus, of 9 reported cases of tracheotomy following intubation, there were 3 deaths, 5 recoveries, and in one the result was not noted; so we have a very good showing, as to the results of this secondary operation. Further, we must not forget that the operation was performed in one-third of the cases after the tube had been worn from four days up, and consequently to them is due some credit for having tided the child over the most critical period of the disease.

That accidents will occur these cases prove, but accidents of just as serious a nature occur during the performance of tracheotomy; in both, however, they are the exception and not the rule.

The above-described accidents suggest to my mind the following queries:

1. What causes will necessitate the performance of tracheotomy after intubation?

2. Can we avoid any of these causes or accidents?

3. Can we tell beforehand whether intubation is going to fail?

The causes which have called for in the past and may in the future call for operative interference are as follows:

(*a*) An intolerance on the part of the larynx to retain the tube.

(*b*) Inability to administer a proper amount of nourishment to the child.

(*c*) A plugging up of the tube with false membrane and mucus, or a dislodgement of pieces of membrane during the process of introduction.

(*d*) A return of the dyspnœa with an absence of the tube from the trachea, as in Dr. Montgomery's case.

(*e*) A wedging of the tube in the larynx, so that it cannot be removed through the mouth.

(*f*) A forcing of the tube, during its introduction, through the floor of the ventricle in place of passing it into the larynx.

Fortunately we can do something to avert the most of these accidents. Spasm of the larynx, as indicated by a short spasmodic cough, along with a frequent ejection of the tube, can be relieved by cracked ice by the mouth and counter-irritation to the neck. In the way of medication, I have found that full doses of belladonna and nitre, with a small dose of chloral, afford speedy relief to laryngeal spasm.

[1] Weekly Medical Review of St. Louis, vol. 15, No. 3, January 15, 1887.

Inability on the part of the child to swallow will, I trust, soon be overcome by some modification of the present tube. As it is now, we can make use of rectal alimentation and skin inunctions, and when necessary we can feed through a rubber catheter.

When we are certain that the tube has been swallowed, tracheotomy could be postponed if we had another tube of the right size at hand. Wedging of the tube into the larynx, or passing it forcibly through the neighboring tissues will only occur where great violence is used by the operator and can be easily averted.

The only truly serious accident which has thus far been met with in the history of intubation is a dislodgement of pieces of membrane during introduction. In any individual case we cannot say whether such an accident will occur, yet it is gratifying to know that it does not happen as often as one would naturally suppose. When one is unfortunate enough to have such a case, after the withdrawal of the tube, the child may relieve itself by coughing, or we may aid it by producing emesis, or by extracting the membrane with a pair of long tracheal forceps, as done once by Waxham, of Chicago, or as a *dernier ressort* we must perform tracheotomy.

In avoiding this accident strict attention to the details of the position of the child and of the management of the introducing instrument, along with great care and gentleness on the part of the operator, will be of some assistance.

Let us hope that the future will reveal to some one of us an improvement whereby this unfavorable accident may be overcome.

Finally, can we tell beforehand whether intubation is going to fail?

I think not, and since it has been clearly shown that intubation is able to accomplish the same result as tracheotomy, in the light of my own experience, and of the expressed opinions of many others, I am inclined to resort to tracheotomy only after I have proved that intubation has failed.

ECZEMA RUBRUM OF INFANCY.

By GEORGE T. WELCH, M.D.,

KEYPORT, N. J.

I HAVE under my care at present a middle-aged lady, weighing three hundred and twenty-five pounds, who is suffering with an aggravated type of eczema rubrum, beginning in the right hand, with all the violent frenzy of erysipelas, and rioting onward over, comparatively speaking, as ample a field as Gengis Khan ever came crowding discursively upon from over the Ural. The heat, swelling, and pain of the skin, together with the rapid march of the disease, combined to obscure the diagnosis for a short time. On the fourth day the inflammation began in the left hand, and ultimately the arms, shoulders, neck, and cheeks were involved, the skin being hot, red and shining, tumefied, blebs forming; there was headache, fever, anxious expression of the countenance, with a temperature of 104°. A dermatologist who pronounced the disease, at the first blush, erysipelas, even in the light of subsequent events, would have been treated leniently in any medical court in the world. For at length the skin excoriated, a true catarrh of the surface began, crusts formed, were exfoliated, drying followed, and light irruptions within the devastated district, followed by pityriasis, is the rule at present.

This disease, with the characteristics I have detailed, occurring in an infant about the genitalia would, in all likelihood, have been diagnosed as erysipelas, and treated, or maltreated, accordingly.

It is, in fact, no easy matter to diagnose between erysipelas and eczema rubrum, occurring in the tender, plastic tissues of infancy. Disease, like a potter, moulds and burns them into strange types, puzzling to the Adam who stands forth to name them.

I have notes of eleven cases of eczema rubrum occurring in infants, beginning at the genitals or at the margin of the arms, and with slow, sturdy invasion, accompanied with heat, pain, tumefaction, marasmus, and diarrhœa, proceeding to spread upward and downward until, in some cases, two-thirds of the surface was involved. As illustrations, I shall briefly sketch some of these cases.

E. S——, female, aged seven months, when seen, June 24, 1882, had a diseased surface, hard, shining, inflamed, radiating from the vulva, three inches in diameter. The child was fretful, feverish, without appetite, and had indigestion. By July 1st the inflammation had reached a diameter of twelve inches, the skin being puffy about the margins of invasion, while at the centre it was hard. This hardness, due undoubtedly to cellulitis, spread outwardly, accompanying the progress of the acuter symptom. By July 12th the inflammation had spread to the knees and upward to the umbilicus and to the margin of the shoulder-blades. In the meanwhile minute vesicles, closely crowded upon each other, especially about the origin of the disease, threw out a delicate, serous fluid, highly corrosive in character, under the influence of which the epidermis became denuded, and the moist, shining cutis, like an extensive scald, received the discharges from the urinary and alimentary canals, adding further torture to the deplorably failing infant. About one-eighth of the surface became thus exposed, and, complicated with other exhausting symptoms, the child died in about six weeks from the date on which I first saw it.

In September of the same year I was called to see B. E——, male, aged two years, in the last stages of this disease. His previous history was somewhat similar to the previous case, as nearly as I could learn it. In place, however, of a moist, denuded surface about the genitalia and buttocks, the cutis was red and dry, covered with yellowish lamellæ; the penis was covered with dried crusts, under which the disease had continued to eat until the organ was distorted and urination was painful. In spite of his terrible ordeal the little fellow was alert in mind, and complained of but little suffering. His death occurred on the third day afterward.

May 27, 1884, H. D——, male, aged six months; when seen was excoriated about the arms, the skin puffy, red, painful, and the inflammation rapidly progressing. During the next six days it had spread upward and downward as far as the middle of the thighs, half way to the umbilicus, and to the dorsal region of the spine. It did not stop here, but more slowly advanced, cellulitis occurring, with stripping of the epidermis from a large space. Diarrhœa began, and the patient slowly sunk; but under the influence of treatment and better hygienic surroundings recovered in about four weeks.

October 16, 1884, G. T——, aged thirteen months, presented the characteristic symptoms at my first visit. The disease was very obstinate and spread over a large portion of the abdomen, the back, and down the thighs, cellulitis occurred to a limited extent, and there was loss of the epidermis over nearly the whole of the posterior portion of the diseased surface. The base of the penis and of the scrotum was thus denuded. Diarrhœa occurred, and aphthous sore-mouth, but the child finally recovered, being declared convalescent November 27th.

In 1886 I saw two cases of this disease in female infants; in neither of them, however, was it so aggravated as in those previously detailed, though in one there was a circumscribed cellulitis about the vulva and anus, with denudation of the epidermis, the inflammation extending to the waist.

In some of the cases I have observed, the temperature in the axilla reached 104°; in all of them there was fever, diarrhœa, a red, shining, inflamed surface raised above the surrounding healthy skin, with excoriations, often extensive, at the origin of the disease. To diagnose this disease from erysipelas is not always easy; in fact, there seems sometimes to be a compound of the two diseases, or they become convertible. The symptoms of either in an adult are likely to be sufficiently defined; but in infancy all is exaggerated, an erythema shades insensibly into an erysipelas, and that subsides as imperceptibly into eczema rubrum. The tender surface seems less a skin than an ethereal mirror, in which the emotions of flesh and blood and nerves picture themselves confusedly. But it may be said that erysipelas spreads more quickly, the swelling is greater, and its subsidence follows usually in from three to five days; in favorable cases some desquamation may occur, but in a majority of cases there is none. Eczema rubrum, though violent in character, with raised and shining cuticle, fever, pricking pain, and cellular hardness, is slower in development, and in about the time that erysipelas would begin to disappear, or prove fatal, it takes on the better-known characteristics of ordinary eczema—the eruption occurs, pustules form, the epidermis is lost about the seat of invasion, while the erythema continues to spread.

Because of the severe constitutional features accompanying this form of eczema in infants—the marasmus and diarrhœa—I look upon it, if much surface is involved, as being of a grave character, and if extensive denudation has occurred, involving the genitals, it may prove fatal.

As to treatment, the cases I have seen have occurred in the underfed and neglected infants of poor and sordid families, and a radical change must be made in the hygienic surroundings. Sour and filthy clothing must be removed, diapers must not be pinned about the child, but the discharges must be received upon napkins laid under the patient, which must be at once changed, and the parts must be gently bathed and dried afterward. Infants with this disease protest vigorously against the contact of water, and it does prove an irritant. Bran-infusion, or water to which glycerine and extract of witch-hazel have been added, or oatmeal-water, is best for bathing purposes, and, after drying, a powder of starch and oxide of zinc may be dusted over the surface. To the denuded part an ointment of glycerole of boracic acid is peculiarly grateful and healing. Spread upon prepared lint and laid over the part is the best way of employing it. Elsewhere lotions containing calamine and oxide of zinc in rose-water or lime-water prove most serviceable. Later on, ointments of oxide of zinc, and finally of mercurial preparations, are more useful.

Internally, emulsions of cod-liver oil, if they do not impair the already weak digestion, are called for, but especially mixtures containing pepsin, dilute hydrochloric acid, and bismuth, with a small amount of opium in some form, suspended in syrup and water, to check the indigestion and diarrhœa. This must be speedily controlled or all is lost. If the mother's milk is unfit for nourishment, condensed milk, with lime-water, barley-water, and a few drops of whiskey, must be substituted. Mellin's food, or Horlick's, or Carnrick's soluble food, or some other approved preparation, will find its place. Beef-peptonoids or Murdoch's liquid food will be called for. The practitioner will be puzzled time and again, but a level head and an extended knowledge of the therapeutics of intestinal indigestion and of eczema will bear him out.

It is no part of my plan to sketch an extended treatment of the disease; rather, I have sought to call a stricter attention to a rare form of eczema in infants, and warn against confounding it with erysipelas, as I have known it to be done, and the consequent mischief resulting from misapplied drugs.

Ovariotomy.—M. Terrillon communicated to the Surgical Society a *résumé* of 35 ovariotomies completed in 1884. Of these 20 were difficult cases; 29 unilocular cysts, 4 parovarian cysts, 1 dermoid cyst, and 1 ovarian sarcoma. Of the 35 patients 6 died. The operations were conducted antiseptically.—*Medical Press.*

Clinical Department.

BERGEON'S TREATMENT FOR PHTHISIS.

Dr. J. R. Brandt, of Chicago, writes: "I have been using the 'Bergeon treatment' for diseases of the respiratory tract since December last, in private practice, also to some extent in Cook County Hospital. I do not feel inclined to make a full report of my cases as yet, but there are several interesting points that have been developed which I think should be made known without further delay: 1. In cases of phthisis caused by inhalation of vegetable or mineral irritants, *i.e.*, workers in wood or stone, the treatment has only given a short relief, and the patients relapsed. 2. In cases of amyloid kidney there was more sudden relapse than in the first cases. 3. In cases where large cavities existed there was no improvement from the beginning. 4. In cases complicated with paraplegia, the treatment was actually injurious, causing violent cephalalgia. 5. In cases of tuberculosis, complicated with tubercular meningitis, treatment has proved a failure. 6. In asthma there was no improvement after the fourth or fifth day.

As to the nationalities of those who showed the most immediate relief, the Norwegians came first, Swedes, Danes, and Germans in the order named, English and Americans of any other descent except Irish, came next. The Irish and their immediate descent came next to last, and last and least helped were the mulatto, and half-breed Indian. Caution: All persons should be carefully examined in order to exclude the cases as above mentioned, as well as those who may have aneurismal varix. In generating the carbon dioxide care should be taken to exclude persons from the room who are subject to asthmatic attacks, as I have seen a violent seizure provoked in a person who was subject to very slight attacks by unfortunately inhaling some of the gas while it was being generated. The following queries have also been suggested to me: 1. Can any, and, if so, what forms of bacteria be cultivated in sulphurous waters, either before or after passing carbon dioxide through them? 2. If the numerous cases reported by Professor Bergeon gave entire satisfaction to the Medical Faculty of Paris, why should M. Cornil institute a series of experiments on dogs, when it had been successful in the highest type of animal life? 3. What is it that really helps the patient? When we reflect that the waters used by Professor Bergeon contain only 0.16 of a cubic inch of H_2S. to the pint, and the waters used by others contain from one to four cubic inches to the pint, and yet all claim wonderful results, may it not be that some of the salts held in solution do much toward the relief? In England, between the years of 1830–32, Professor Lata and Dr. Stevens injected into the veins of cholera patients solutions of the muriate and carbonate of sodium from thirty-one to forty pounds within twenty-four hours, with the most interesting results (see Pereira's 'Materia Medica,' p. 313)—restoration of pulse and of consciousness, and feeling of well being, etc.; yet they all died just the same, and of cholera."

TWO CASES OF FRACTURE OF THE SKULL—RECOVERY.

Dr. Thomas H. Manley, attending surgeon to the Harlem Hospital, reports the following cases: "John S——, nineteen years of age, suffering from the results of a kick by a horse, was brought to the Harlem Hospital on March 29th. Examination showed a large chasm on the left lateral aspect of the skull. The smashed bone was crowded down into the brain substance, and some of the fissures of the shattered bone were filled with hair, and others with fragments of the dura mater and cortical substance of the brain. There was not much hemorrhage. As nearly as could be defined, the fracture extended through the parietal bone posterior to the coronal suture, involving the anterior junction of the temporal with the parietal, just above the temporal ridge. The wound was about two and a half inches in length by one and a half in width. When the patient was received he was unconscious and suffering from evidences of concussion. The pulse was slow and hard, the body was covered with a cold, clammy perspiration, and the pupils were widely dilated. The smaller fragments of bone were first lifted out, and then the larger pieces raised up by the bone elevator. The protruding brain substance that could not be replaced was removed by the scissors. The edges of the dura mater were then carefully approximated and secured by catgut sutures after the wound had been thoroughly washed with antiseptic solutions. A horse-hair drain was inserted beneath the scalp, and the scalp itself was closed with strong catgut sutures. The following day the patient was found to be very childish, crying on the slightest provocation, and was also aphasic. He was able to articulate clearly, but could not speak connectedly, using the wrong words constantly. He recognized his father, and seemed to take an interest in what was going on around him. There was considerable discharge in the dressing, but no pus. Temperature normal, pulse about 90. Paralysis of the right arm supervened, but gradually disappeared along with the aphasia. The wound healed readily without complications, and the patient made a good recovery. There was a slight degree of hernia cerebri, which gradually receded.

"The second case was that of a man, twenty-eight years of age, who had received a fracture of the cranium from a blow with a bar of iron. It was a depressed fracture situated just over the temporal ridge, three and one-fourth inches in length and three-fourths of an inch in width, commencing on the frontal bone and extending to the parietal. On admission the man was unconscious, breathing stertorously, the face was of a deep-red color, the eyelids were drooping, and there was a divergent squint. An attempt was made to raise the bone without trephining, but was unsuccessful. Then the trephine was applied and a small button of bone was removed. The teeth of the instrument pierced the cortical substance of the brain, lacerated the dura mater, and caused some hemorrhage. It was now found that the fracture, though extensive on the surface, involved the external table only of the skull, and no break in the inner table could be discovered. The line of incision was closed with continuous catgut suture, provision being made for free drainage. On coming from under the influence of the anæsthetic, the patient was found to be conscious. He vomited some dark blood-clots during the night, and was unable to retain anything on his stomach all the next day. He was rational and slept the greater part of the time. On the third day the man had three convulsions of an epileptic character; he was aphasic and had some squinting. The convulsions recurred again on the following day, but not after that. The wound healed readily, the temperature rising only once above 100°.

"Both these cases were brought into the hospital at about the same time, and both, though sustaining wounds of an altogether different character, were affected similarly as regarded the loss of speech. The first man, although much the more seriously injured, did not lose consciousness until after he had been brought to the hospital. At about the fifth day in each case there was a noticeable improvement in the power of language. The temporary paralysis in the first case was of short duration, and was confined to the upper extremity. The second patient had all the symptoms of a serious lesion, although no such lesion was present. The presumption was that there was bone pressing into the brain substance, and probably hemorrhage, but the sequel proved that there was neither. In this case it was impossible to

say whether the cerebral symptoms observed were due to the injury or to the operation. The writer states that he is inclined to the opinion that they were due rather to the latter."

TWO ADDITIONAL CASES OF SPONTANEOUS DELIVERY IN PLACENTA PRÆVIA.

Dr. Alfred Hinde, of Chicago, Ill., writes: "After reading the interesting reports of cases of placenta prævia in recent issues of The Medical Record, I venture to forward you the notes of a case which occurred recently in my own practice, and which terminated spontaneously. On April 19th last I was called to see Mrs. F. H——, forty-two years of age, a robust Englishwoman, in her eleventh gestation, and then in the eighth month of the same, and was told that 'the waters had broke' forty-eight hours before, and that a slight sanious tinge was now present in the continuous leakage. I made a digital examination and found the characteristic multiparous cervix, but the internal os was not perceptibly open. The fœtal heart-sounds were very distinctly heard above and to the left of the umbilicus. The condition of the patient was good, and there was no uterine pain present. I suspected placenta prævia and elicited the information that in a former pregnancy she had flowed for about a week previous to labor. On April 21st, two days later, a distinct hemorrhage commenced, and this continued in slight but variable amount until the noon of the 24th, when it became suddenly severe and intermittently continued for six hours. I saw the patient at this time, and she complained of faintness, with slight thirst, and was sighing and retching frequently; pulse 98. The bed was saturated with blood; the vagina was filled with clots, and the os uteri was about the size of a silver dollar—soft, cool, moist, and dilatable, and with the boggy placenta presenting. Fearing the recurrence of severe hemorrhages, and having witnessed death from such cause in a similar case, where the post-mortem plainly revealed that, had a timely termination of the gestation been pursued, a most probable favorable result to the mother would have been attained, I thought seriously of at once dilating the os, separating in part or *in toto* the placenta, and withdrawing the same if advisable, and, lastly, turning and delivering the viable child—using ergot to excite and maintain uterine contractions. Counsel stated that my proposed course of procedure, though possibly the correct one, and probably offering the best chance for the mother and viable child, yet was unorthodox; and seeing that uterine action was slight, the hemorrhage at this time of small amount, a waiting course was advised. I deferred to this opinion, and, after the administration of an opiate and counselling quiet, left the case. About thirty hours later I was hurriedly summoned by the husband, who told me that severe pains had commenced, and that the flow, though continuous since my last visit, had only been slight in amount. On reaching the bedside I found the child born and the uterus well contracted, and, consequently, no hemorrhage other than normal was present. The nurse said the child had been born about fifteen minutes; that severe pains had started in about an hour previous to the birth, and that with the third pain the child was born. I waited a quarter of an hour, and then readily expressed and delivered the placenta, and thus completed the labor. The placenta on careful examination was found to be entire and healthy, and showed one-half its bulk to be ecchymosed, shrunken, and the uterine surface of this half was covered with blood-clots. Thus, to the very gradual dilatation of the os uteri, together with the slow separation of the cervical placenta and the thorough plugging of the venous sinuses, together with a precipitate labor, we may attribute the happy termination of this case. The further progress of the case was strictly normal. Here we have the notes of two placentæ prævіæ occurring in the same individual, and both terminating favorably to the mother without professional interference."

Dr. B. P. Reese, of Staunton, Va., reports a second case of this nature, which occurred in his practice at about the time that the account of the first case appeared in these columns. The patient, thirty-four years of age, had been married four years, and had had one miscarriage. She had had frequent slight hemorrhages for some time. The vagina was very long, and it was nearly impossible to reach the os uteri with the examining finger, but a diagnosis of placenta prævia was made from the obstinate bleeding. Dr. Patterson saw the case in consultation and confirmed the diagnosis. Tampons wet with Monsell's solution were introduced daily. About a week after the case was first seen slight pains began and the hemorrhage increased. Sometimes a severe pain would force out the tampon, and the bleeding would then increase. After the os was dilated to the size of a half-dollar, the placenta could be plainly felt covering about one-half the opening. The placenta came away without trouble after the birth of the child. During the three weeks following, the patient did very well; but one evening at the end of this time, after she had been sitting up in bed until she was tired, her husband took her in his arms and put her in a chair. She at once fainted, and it was long before she was restored to consciousness. She seemed never to rally wholly, but died the following day.

THE TREATMENT OF INTERNAL HÆMORRHOIDS BY INJECTION.

Dr. Q. A. Shuford, of Tyler, Tex., sends the following communication: "In the treatment of internal hæmorrhoids by submucous injection, it is necessary, in the first place, to have an instrument that can be introduced with the least amount of pain, and so constructed as to expose as much of the mucous membrane as possible. When a tumor is discovered, the speculum should be manipulated so as to bring the centre of the tumor into plain view, and the needle should puncture the pile at this spot, as it is here less sensitive than elsewhere. This requires a long needle, which should have a guard near the point, so as to prevent it from entering too deeply. For small tumors I inject from three to five drops, and for larger ones from five to eight drops of the following mixture: Rub well together one drachm of salicylic acid and one and one-half drachm of glycerine, and add two drachms of carbolic acid; then rub together one drachm of borax and one and one-half drachm of glycerine, and mix the two thoroughly, allowing the mixture to stand until clear. The chemical changes and *modus operandi* of this combination I do not know; but I do know that internal hæmorrhoids treated in this way become atrophied, shrink up, and peel off without pain, inflammation, or suppuration. I have never had any trouble nor heard any complaints from patients so treated. The two essential points in the treatment of internal hæmorrhoids are: first, an instrument that will bring the parts to be treated into view, and that without pain; and, second, a remedy that will completely destroy the pile, while leaving the mucous membrane in a healthy condition. An interval of from eight to ten days should be allowed to elapse between the injections, so as to give the mucous membrane time to become toughened. The injections cause almost no pain, and do not prevent the patient from pursuing his ordinary avocations." Dr. Shuford reports several cases treated after this method, and adds that he has treated nearly one hundred, of varying degrees of severity, and in none has he seen any inflammation or suppuration following the injections.

To Preserve Bichloride Solutions from precipitation, add seven and a half grains citric acid to each quart of the solution.

Progress of Medical Science.

Hydrastis Canadensis in Uterine Hemorrhage.—Hydrastis Canadensis, or Golden Seal, has been long used in this country as a pure bitter in atonic dyspepsia. The root of hydrastis contains berberin and hydrastin, both of which are believed to have a vaso-constrictive action on relaxed mucous membranes, thus ameliorating congestive states (*Boston Medical and Surgical Journal*). Professor Schatz, of Rostock, Germany, was the first to bring hydrastis prominently before the medical public as a uterine tonic. He contrasts it with ergot, which it resembles in its action, but he finds it efficient in cases of uterine hemorrage where ergot is powerless. In menor rhagia from whatever cause, in hemorrhages due to metritis and endometritis, to myoma, to incomplete involution of the puerperal uterus, he has found hydrastis invaluable. Professor Schatz's mode of administration is to give the fluid extract in twenty-drop doses four times a day, and not only when the hemorrhage continues, but also from one to two weeks prior to the time that the menstrual period sets in, especially in the congestive form. Since the publication of the paper of Professor Schatz, Professor Slaviansky, of St. Petersburg, has made some interesting experiments with hydrastin, from which he has found that this alkaloid has an ecbolic effect on pregnant animals (bitches and rabbits), and when given to parturient women it expedites labor. He puts the maximum dose of hydrastin at one-half grain. The latest contribution to the subject of the uses of hydrastis in uterine hemorrhage is by Dr. R. W. Wilcox, in the New York *Medical Journal*. His conclusions are based on the observation of the effects of this in fifty cases. In three of uterine fibro-myomata, in which he gave hydrastis for metrorrhagia, the flow was speedily checked. Persistent use of hydrastis (for months) was followed by considerable reduction in the depth of the uterine cavity and in the volume of the uterus. Wilcox concludes that hydrastis arrests the bleeding from fibromyomata by the production of anæmia of the uterine tissues, and he refers to the physiological experiments of Mays, which showed "that hydrastin in small doses increased blood-pressure, while causing vaso-motor contraction, cardiac inhibition, and anæmia of the alimentary mucous membrane. Mays observed also uterine contraction, even of the body and horns of the uterus." Fellner, moreover, in some experiments made in 1885 with fluid extract of hydrastis, noticed uterine contractions and anæmia of that organ. In seven cases of hemorrhagic endometritis, five being cases of endometritis fungosa, marked benefit was noted under the use of hydrastis. Dr. Wilcox remarks that "in endometritis fungosa, we have in hydrastis a sovereign remedy, even when curetting has failed to arrest the bleeding." Sixteen cases of subinvolution of the uterus were treated satisfactorily with hydrastis. Five cases of climacteric hemorrhage were also benefited by the same drug, and the same is said of nine cases of pelvic inflammation and three of congenital anteflexion. He gives the fluid extract of hydrastis in twenty-drop doses three or four times daily in a wineglassful of water.

Phosphatic Diabetes.—At a recent meeting of the Medical Society of London, Dr. Ralfe read a paper on this subject. He arranged his cases in groups according to the classification of Professor Teissier, who first gave a systematic account of the affection. Group 1. Excessive elimination of phosphoric acid associated with nervous derangements; three cases. Group 2. Excessive elimination of phosphoric acid associated with phthisis; three cases. Group 3. Excessive elimination of phosphoric acid alternating with saccharine diabetes; three cases. Group 4. Excessive elimination of phosphoric acid running a distinct course, like saccharine diabetes, only without the sugar; five cases. All the cases, with the exception of two, were young adult males. The symptoms common to all were great emaciation, aching rheumatic pains in loins and pelvic regions, dry, harsh skin, with tendency to boils, and ravenous appetite; in some cases cataract develops. In the majority there was polyuria; in others the urine was normal in quantity, with a high specific gravity. The urea was increased in some cases slightly, in others to a greater extent; but the great feature of all the cases was the very considerable and constant elimination of phosphoric acid, with or without increase of the other constituents of the urine—a feature which distinguishes it from insipid diabetes on the one hand, and azoturia on the other, with both of which it has been improperly confounded. The pathology, Dr. Ralfe thinks, depends not so much on increased metabolism of nervous matter as on defective nutrition, so that the tissues are not able to utilize the phosphorus brought to them, and consequently a greater amount passes through the system daily. In those cases in which an excessive excretion of phosphoric acid replaces saccharine diabetes, it is probable that acids like oxy-butyric-glycollic, etc., formed by imperfect oxidation of the sugar, dissolve out the earthy phosphates from the tissues, which appear in excess in the urine. As regards the prognosis in these cases, it is most unfavorable in the first two groups; country air, massage, cod-liver oil, may for a time do good, but the patients rapidly fall back, and either are carried off by some acute attack proving fatal in their exhausted condition, or drift on to phthisis, or into diabetes mellitus. The prognosis of the last two groups is much more favorable.—*The Lancet.*

Comparative Virulence of Tuberculosis and Scrofula.—At a recent meeting of the Académie des Sciences, M. Arloing made some remarks on the virulence of tuberculosis and scrofula. He had already shown that pulmonary tuberculosis infected guinea-pigs and rabbits, while true glandular scrofula had no effect on the latter animal. M. Arloing now inquired whether the virulence of scrofula might not be increased to such a degree as to permit the infection of both these animals. Experiment proved that the passage of scrofula through two generations of guinea-pigs did not increase its virulence in respect to the rabbit, and did not perceptibly modify its action upon the guinea-pig itself. The organism of the guinea-pig, on the other hand, augmented the virulence of the weakened tuberculous virus. This fact shows that there is a decided difference in the two diseases, although it has not yet been proved that they are caused by two distinct kinds of virus.—*British Medical Journal.*

Orchitis in a New-born Child.—Dr. Reid writes as follows in the *Australasian Medical Gazette*: "The child was brought to me on November 20, 1886. The mother said it always had a cold (snuffles), and that the woman in attendance at the birth noticed the left scrotum large, but said it was nothing. There were ulceration at the navel, slight bronchitis and thrush, with snuffles to a small extent. The scrotum on the affected side was congested at parts, boggy in feel, and very slightly, if at all, tender, as if containing fluid, opaque, and the testicle was enlarged uniformly to about once and a half the natural size. Under mercurial inunction testicle and scrotum reached their natural size on the 25th. On the 26th, change of weather metamorphosed the bronchitis, which they refused to have treated, into broncho-pneumonia (catarrhal pneumonia), and the child, at the age of fifty-five days, died at midnight from exhaustion. There was no autopsy. The parents have been healthy, and the brothers and sisters, although pasty in appearance, have never exhibited signs of syphilis. The teeth are slightly notched in some of the children. A brother survived a severe attack of typhoid complicated with pneumonia, but uninfluenced by mercurials. Mother's brother (uncle) was treated for over a year for psoriasis of the leg, which

yielded to anti-syphilitic treatment with chrysophanic acid locally applied. He denied ever having had connection, and his age is twenty-three. Thus, if the disease is syphilitic, which I believe it to be, from the uniformly enlarged, hard testicle and the presence of snuffles, it must be the product of latent syphilis, just as that of its uncle was. From the life of the uncle, J. A. F——, I have reason to believe his statement, and also his assertion when he said he never suffered since childhood. There was no known cause of injury; the labor was natural."

Urinary Infiltration.—Dr. Picard states that the prognosis of any given case of urinary infiltration is to be based upon the quantity and quality of the infiltrated urine, the extent of the infiltration, and the general condition of the patient (*St. Louis Medical and Surgical Journal*, April, 1887). The larger the amount of urine, the worse the condition; the more dense it is, the greater will be the irritation it causes; although less than if ammoniacal, as it will then prove septic. If the involvement be rapid, it shows that the urine came in a forcible stream, and this implies a laceration of tissues. The treatment of urinary infiltration consists of evacuating the urine and re-establishing the normal canal. To accomplish the first purpose, the writer recommends an incision in the median line of the perineum, encroaching somewhat upon the scrotum and continued up to within a half inch of the anus. The tissues to be incised are: the integument, the subcutaneous connective tissue, and the superficial fascia. Secondary incisions are also to be made, not deeper than the cellular tissue. Portions of necrosed tissue will accompany the escape of the fetid urine, mixed with sanious pus. Antiseptic dressings are to be applied. In about two weeks or a month the question of re-establishing the normal canal may be considered. Efforts should not be made before this, because the disturbances caused by the urine have not disappeared, and any attempts on the urethra might be attended by a chill, fever, and even septicæmia or purulent infection. As to the method of restoring the urethra to its normal calibre, the surgeon must decide for himself. Progressive dilatation or internal urethrotomy will give good results, if used firmly and judiciously. Cases that appeared to be hopeless at first will become entirely well if the urinary infiltration is properly managed before any surgical interference is brought to bear on the urethra.

The Nature of Coma.—Dr. Mercier has recently published an interesting paper on this much-discussed topic. *The Lancet* of March 5, 1887, comments as follows upon it: "Dr. Mercier accepts, with one slight modification, Mr. Savory's definition of coma, as a 'state of insensibility from which the patient cannot be completely aroused, together with a tendency to death, chiefly by asphyxia,' the modification being the substitution of the phrase 'evidence of defect of consciousness' for the term 'insensibility,' as being more correctly descriptive of a state in which it is impossible to determine whether or not consciousness is absolutely lost. He points out that the failure of respiratory power is due to the same condition of powerlessness and loss of muscular tone that pervade the whole organism in the comatose state. The skin is relaxed and flaccid, the pulse is full and soft, the bladder contracts sluggishly, the pupils may have lost all power of contraction, and all the limbs are paralyzed, the muscles being quite flaccid. The comatose patient is not inert because he is unconscious, but because he is actually paralyzed. The cardiac muscle alone does not share in this universal paresis. From this condition of complete coma to that pre-comatose period marked by the slightest mental confusion and bodily weakness there are all gradations, as may be seen, for example, in alcoholic poisoning. The phenomena of drunkenness in all its stages exhibit an unbroken chain of gradually deepening lesion of the higher cerebral functions, which enable us to trace the relations of the condition we call coma to the slight perturbations and deviations from the normal condition that mark the earliest changes due to the action of the poison on the brain. As Dr. Hughlings Jackson has pointed out, the paralysis is first that of a loss of movements rather than of motion; the more elaborate actions go before the coarser; the breathing fails before the heart, and the accessory parts of the breathing apparatus fail before the fundamental. It consists in 'a long process of degradation, the last point of attack being the heart, and the penultimate the breathing.' Incidentally Dr. Mercier indicates a pathognomonic sign of true coma, which depends on this loss of muscular control, and that is the movement of the eyes independently of one another. As with the bodily so with the mental functions. The progress of coma is marked in the one as in the other by a gradually increasing enfeeblement. At first there is difficulty in performing delicate mental operations, and then inability for any coherent thought, and, lastly, evidence of loss of consciousness; no response to impressions from without, no evidence of response to impressions from within. And this coincides with the relaxation of muscular tone, the ataxia passing into paralysis; so that the power to execute voluntary movement fails *pari passu* with the failing intelligence, and suggests overwhelmingly the inference that both mental and bodily defect are due to the same lesion. And, it is pointed out, the whole organism is affected—evidence, again, that in the highest centres of the brain we have to do not with any specialized and circumscribed areas of 'localization,' but with a region where the various parts of the body are all represented in some degree, the region of consciousness and of the organism as a whole. Dr. Mercier implies that in the modern doctrine of 'nerve-centres' we run a risk of losing sight of this fact or principle, that the whole organism is represented, and therefore to a certain extent controlled and knit together through the highest nerve-centres—a principle which is so clearly manifested in the phenomena of coma, and just as clearly in the phenomena of insanity. For insanity is linked with defects in the nutrition of the body; it runs its course, both as regards mental faculties and bodily functions, in the same direction and with the same pathological sequence as does coma, in which it often finally terminates. But if coma be a form of insanity it is a 'fulminant' form; and if insanity be expressed in the terms of coma it would be that it is coma long drawn out. The underlying principle in Dr. Mercier's argument is that the higher brain centres, where consciousness is aroused by impressions from within and without, and where the will is born of intelligence, and action expresses the response of the conscious will to the environment—that there, where all the bodily functions must be represented, is the seat of the lesion that suddenly or gradually breaks the chain between the individual organism and its surroundings, and may profoundly affect those functions which, under the control of the nervous system, are essential to the life of the organism. Possibly this region is conterminous only with the whole of the cerebral cortex; but this does not detract from the suggestiveness or truth of the proposition that 'whether in origin, or in cause, or in termination, coma and insanity are pathologically and symptomatically identical, and the only important difference between them is the difference in duration.' They each illustrate the law of dissolution."

Dying at the Ebb of the Tide.—The *Medical Press* says that a physician living on the seaboard thus writes to a paper: "Within the last five years, in a district embracing sixty square miles or so by the sea, I have noted the hour and the minute of no less than ninety-three demises in my own immediate practice, and every soul of them has all gone out with the tide, save four who died suddenly by fatal accident."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 25, 1887.

THE NAVAL MEDICAL SERVICE.

FROM time to time attention has been drawn in some of the medical journals to the undesirableness of the naval medical service as a career for physicians.

Although many of the articles upon this subject have been somewhat highly colored, it is only too true that the compensation offered by the Government is disproportionate to the requirements of the service, which are so great (and necessarily so, if the medical officers of the navy are to be more than mere place-holders) that it has been impossible for some years to supply the natural waste of the corps from the material presenting itself for examination.

It cannot be surprising that young men of good attainments, who have shown themselves to be worthy members of a serious profession, should object to entering a service in which their merits receive such scant recognition. The "relative rank" given them is the lowest possible, and they are forced to live in a "steerage," the discomforts and complete unfitness of which, for a man intrusted with important duties, are difficult, for one who has not had the experience, to realize.

The steerage stage is over in three years, and then, if they successfully pass their examinations for promotion, comes a period of weary waiting for dead men's shoes before the grade of surgeon is reached; at the present rate of promotion this finds the "passed assistant" about forty years old, having lived during this time on the small pay allowed that grade, practically less than that of an acting volunteer assistant surgeon in the army. It can hardly be supposed that Congress intended that this should be, since promotion was very much more rapid when the present pay-table was made than it is now.

The position of the younger medical officers waiting for their promotion is not made more pleasant by the contrast between themselves and their army *confrères* who have a satisfactory status in the service, and receive a compensation that naval surgeons would be glad to exchange for their own.

The army medical officers have undoubtedly managed things better than their brothers afloat, but the latter can hardly be accused of apathy or lack of effort to improve their condition.

The obstacles that naval surgeons have had to contend with and against which their struggles have so far been futile, are, in the first place, the smallness of the corps, which at the present writing contains only one hundred and seventy-three members, and their enforced isolation from the mass of the profession, with whom, from the nature of their duties, they can rarely come into intimate contact. Consequently their colleagues on shore almost lose sight of them, and allow them to work out their own salvation.

Another reason why they have fared so much worse than those of the army, is that the traditions of the navy —which was originally modelled upon the English navy system, when the aristocratic idea that it was beneath the dignity of gentlemen to engage in the practice of medicine prevailed—are all strongly inimical to staff officers, and have prevented them from obtaining substantive rank. This means much more than the mere satisfaction of the desire for sounding military titles, as anyone at all familiar with the working of a military organization will readily understand. In this respect our navy has fallen behind, not only our own army, but even its original model, the English navy, in which the position and pay of medical officers are relatively much better than in our own.

The terms "combatant" and "non-combatant" officers, which are persistently employed by the line, with the view of making a sharp distinction between themselves and the staff, and thus preventing the acquisition of substantive rank by medical officers, are illogical and misleading ones. Either every man who performs services essential to the efficiency of a fighting organization, and exposes his life in action, is a combatant in the broad sense of the word; or, if the term is to be limited to those who actually do the killing, the men who pull the triggers and lock-strings are the only combatants. Indeed, the fighting strength of a force is often estimated by the number of "muskets" in line ot battle, none of the officers being reckoned at all.

The records of the war show that the loss of life in action was proportionately much greater in the medical corps of the navy than in the line or any other staff corps.

Surgeons in the navy are subjected to exactly the same regulations and discipline as those that govern the line, rule their departments by military law and methods, incur the same perils in war, greater ones in peace, and are yet deprived of many privileges and subject to many galling distinctions because they do not have the substantive rank that army surgeons enjoy.

The medical officer who is killed in battle in the discharge of his duty is docked of part of the military funeral honors that are paid to his comrade of the line, and this childish and ungenerous distinction is kept up for no better reason apparently than that it wounds, or is supposed to wound, the *amour propre* of the staff.

If Congress would grant to naval medical officers that which they have already given to those of the army, such distinctions, many of them more substantial and harassing than the one above mentioned, would fall to the ground, and the struggle between the factions would cease, as the experience of the army has shown.

To those who read the bitter complaints of the English army medical officers, which are now appearing in their medical journals, *à propos* of the recent abolition of even their shadowy "relative rank," it should be ap-

parent that actual rank is almost a necessity of military life, and that all officers who are of a military organization without it feel constantly and keenly the need of the well-defined status that only such rank can give.

The surgeons who go into action with the first line of infantry, or gallop with their regiments wherever they go, if serving with cavalry, as their instructions require them to do, know that they should have this rank, or else, if they are "civilians," as some of the line contend, not be compelled to put their lives in jeopardy, or be subject to military law and discipline.

It is more than probable that the English army medical staff will finally gain its point, for behind it is the active interest of the medical profession and their most influential societies and journals, which must in the end, make itself felt in Parliament. With anything like such support from the profession at large in this country, the rightful claims of the medical officers of the navy could hardly fail to be granted, and these claims are simply that they shall be placed on the same footing and receive the same compensation as those of the army.

That members in good standing of a liberal profession should be in a position so unsatisfactory, in one of the principal services of the Government, is a reflection upon that profession that should, if the facts are ever generally known, excite interest enough in its members at large to induce them to use their great influence with Congress to improve this condition. Meanwhile naval surgeons must possess their souls in patience, for without the aid of their professional *confrères* outside of the service, their struggle upward must be a hard, and, for a long time, almost a hopeless one.

OUR NATIONAL HOLIDAY: A TIMELY SUGGESTION.

As that day approaches on which the irrepressible American small boy gives free vent to his enthusiasm, while at the same time his toy-pistol lodges sundry foreign bodies in various parts of the anatomy of self and friends, a word on the appropriate treatment of those small, but by no means unimportant, injuries which attend the Fourth of July may not be out of place.

The frequency of these injuries is within the knowledge of every practitioner in city or country—so, also, the fact that in a certain proportion of cases septic processes—cellulitis, septicæmia, pyæmia, or tetanus—complicate the wound.

The first is by no means rare, while the mortalities presented by the daily press during the month of July headed, "The Deadly Toy-pistol," show that the latter are far too common.

These wounds are small, but their treatment is a matter of importance, and should be carried out as follows:

As soon as possible after the receipt of the injury the parts about the wound should be thoroughly cleansed with an antiseptic solution of sufficient strength, preferably the bichloride of mercury, one part in one thousand. A free incision should then be made at the site of the wound to its bottom, all foreign bodies removed if possible, the bottom and sides of the wound thoroughly *scrubbed* out with the bichloride solution and loosely packed with gauze wrung out in the same. The dressing should be changed often, say, twice a day at first, and the wound will quickly close. The injection of a few drops of the four per cent. solution of cocaine will allay pain and permit thorough procedure.

Under the "expectant" plan of treatment cellulitis will generally reward expectation; if the antiseptic measures described above be sufficiently radical it cannot develop, but, as in all antiseptic surgery, success depends on the degree of thoroughness with which the details are carried out.

News of the Week.

NINTH INTERNATIONAL MEDICAL CONGRESS.—The Executive Committee of the Ninth International Medical Congress held a full and harmonious meeting in the Palmer House, Chicago, on the 6th and 7th inst. Full reports were made by sub-committees and the chief officers of the Sections, which showed a most satisfactory degree of progress in all the necessary arrangements for a large and successful Congress. The several Sections are well organized, and for the most part with arrangements for an abundance of scientific and practical work of importance, furnished in fair proportion by parties of reputation in other countries. The local arrangements at Washington are also rapidly maturing, and include not only the best possible accommodations for the regular work, but a series of appropriate entertainments and probably an excursion for the foreign guests to Niagara Falls and return to New York, after the close of the Congress. An outline of the whole programme will soon be given to the public.—*Jour. of Am. Med. Assn.*

DR. SENECA D. POWELL has been elected Professor of Clinical Surgery in the New York Post-graduate Medical School and Hospital.

THE RETREAT FOR THE INSANE at Hartford, Conn., in publishing its annual report classifies its patients according to the etiology of the disease. Such a method gives a much better idea of the kind of cases than the older symptomological classification commonly used.

BRAIN TUMOR AND ALCOHOLIC COMA.—Three young internes of the Newark City Hospital have received a very severe lesson. A patient was brought to the hospital comatose. He was thought to be suffering from alcoholism, and he was treated accordingly, being given a douche and strong cutaneous irritation. The patient died, and on autopsy there was found a tumor of the brain. A coroner's jury investigated the case, and the internes were thereupon arrested for manslaughter.

THE VIRGINIA STATE MEDICAL SOCIETY is to meet at Richmond on October 19, 1887.

HARVARD MEDICAL COLLEGE.—Dr. C. B. Porter has been appointed Professor of Clinical Surgery, and Dr. J. C. Warren, Associate Professor.

THE USE OF OPIUM IN COUNTRY TOWNS.—Dr. Henry Boynton, of Woodstock, Vt., in a recent address on alcohol and opium, said that the use of opium was increasing in that locality. The four druggists report sales of opium in a year sufficient to make one hundred gallons of laudanum. This is the equivalent of one hundred and sixty-seven ounces of morphine. Of this whole amount only *five per cent.* is sold to physicians.

Jubilees and Medical Journals.—The *Hospital Gazette and Students' Journal* is, we believe, the only successful students' medical journal in existence. The June 4th issue comes to us with a jubilee supplement.

Do not Speak Lightly of a Physician.—A suit was recently tried in Brooklyn, which shows that it is not always safe to speak lightly of a physician. Dr. W. J. Cruikshank recovered a $1,600 verdict, in his suit for $50,000 damages, against William Gordon, the trial of which was brought in the Supreme Court. The doctor asserted that Mr. Gordon went to the mother of a child he was attending, and urged her to secure another physician without delay, as, in his opinion, Dr. Cruikshank had not the skill necessary to attend a sick dog.

Professor Billroth's Recovery from an alarming illness has been the subject of wide congratulation. "Billroth's popularity," says the *British Medical Journal*, "is due, of course, in the first place, to the combination of exquisite operative skill with scientific culture of the best and widest kind, which makes him almost a unique figure in contemporary surgery. His professional gifts and acquirements are, however, largely aided by social graces of a sort not usually associated, in this country at any rate, with eminent surgeons. Billroth is a piano-player of repute, and is, or perhaps we should say has been, almost as agile a performer with his feet in the ball-room as he is with his hands in the operating-theatre. He is, in fact, quite one of the social stars of the imperial city, a position which he owes quite as much to the charm of his manners as to his celebrity. His purse is always open to private as well as public charity. The enthusiastic devotion of his pupils is founded not altogether on his success as a teacher, but also on many acts of individual kindness, all the more appreciated that they are known only to the recipients."

The Abuse of Medical Charity.—We are requested by the Executive Committee of the German Dispensary to publish the following: "June 9th we sent to the office of the Charity Organization Society the name of a patient, for investigation, who had presented herself and child at the skin department for gratuitous treatment, stating that she was unable to pay a doctor. Two days later we received the following report: 'Man very indignant at wife for taking child to dispensary. Told visitor it was done in his absence; has a large business and is abundantly able to pay.'"

Druggists, Dentists, and Doctors.—Massachusetts compels the registration of pharmacists, and recently the legislature passed a law providing for the registration of dentists, but the doctors are left alone.

Malaria and Tobacco.—A Western medical writer has discovered a new and dangerous source of malaria to be the cigar made of tobacco grown in malarial regions. He thinks the recent invasion of the New England States by malaria due to the increased use of Southern-grown tobacco and Southern-packed cigars.—*American Practitioner.*

The Latest Results of Yellow Fever Inoculations communicated by MM. D. Freire, Paul Gibier, and Ribourgeon to the Académie des Sciences, show that among 6,554 persons inoculated the mortality from yellow fever is 1 per 1,000; among those not inoculated, 1 per 100.

Medical Men and the Press.—A recent decision in the French courts shows that in France, at any rate, a somewhat stricter check is placed on journalistic indiscretions when medical men, or their practice, is impugned than obtains here. The *Echo de l'Est*, having announced that a certain person had succumbed to the effects of an operation performed by Dr. Bernard, of Thiaucourt, this gentleman brought an action for libel. The Court of First Instance called upon the writer of the incriminated paragraph to furnish proofs in support of his allegation, but, on appeal, this decision was reversed and the journal was ordered to pay £400 damages, on the ground that the subject matter "was based on a fact of an essentially private nature, altogether outside public discussion, and not amenable to journalistic criticism." The proprietors of the journal will doubtless show a little more caution in future in receiving and publishing items of news reflecting on the reputation of medical men.—*Medical Press.*

Jersey City Hospital.—Six physicians on the visiting staff of the Jersey City Hospital have handed in their resignation to the Police Board of Jersey City, the cause of this action being the interference of the latter Board in increasing the staff by the appointment of eight additional physicians and surgeons. This leaves only two members of the old Medical Board, Dr. Reeve and T. R. Varick.

Appointment of Hospital Physicians in Chicago.—The Board of County Commissioners has recently removed the appointment of the attending staff of the hospital from the domain of politics. It has voted the present staff shall remain during good behavior, and that any vacancies in its membership shall be elected by an Advisory Board of five medical men, whom it has appointed. In case of a vacancy, the staff is to nominate three persons, from whom the Advisory Board is to elect one. The Advisory Board, as at present constituted, has a representative from each of three regular medical colleges.—*Medical News.*

The Prince of Wales and the Typhoid Fever.—Sir William Gull spoke recently of his disbelief in drugs, and referring to the share which he bore of the responsibility of conducting the treatment of the Prince of Wales' attack of typhoid fever, stated that during the whole illness his Royal Highness did not take four doses of medicine. To which a country practitioner replies, in *The Lancet*, "But what if the Prince's illness had been rheumatic fever or malarial fever caught in India (supposing his Indian tour to have taken place), would Sir William still have withheld all treatment by drugs—salicylates in the one case, quinine in the other? I will do him the justice to say I do not believe he would. But is it a fact that the treatment of the Prince consisted entirely in guarding him from interference with the powers of nature, and in keeping him in a warm bed? Was not alcohol freely administered? I do not know; but this I do know, that Sir William regards a full dose of alcohol, two ounces or even four ounces of brandy if necessary, at bed-time, as the best sedative for the nocturnal restlessness accompanied by delirium which oc-

curs in typhoid; and I would ask what is alcohol administered in this way but a drug?"

Increased Mortality in New York.—During the three months ending March 31, 1887, there were 35 deaths from small-pox, 572 deaths from measles, against an average of 219 deaths during the same period in the previous five years. Of diphtheria there were 559 deaths, against an average of 379 in the same period; of croup 313 deaths, the former average being 232; 141 deaths from scarlatina, against 134 in the same period last year; 62 cases of typhoid, against an average of 52 cases for the previous five years, and 592 of bronchitis, against an average of 520. All these point to an increasing proportion of mortality from the most destructive ailments. The deaths of children under one year and those between one and five years are as follows:

	1887.	Average for five years.
Deaths under one year.....	2,088	1,904
Deaths between one and five years ..	4,098	3,611

Increase in deaths under five years nearly ten per cent. —C. F. Wingate, in *Morning Journal.*

A New Sword-Handle.—Professor Braune, of Leipzig, after a thorough investigation of the mechanism of the hand, has constructed a new sword-handle on anatomical principles which exactly fits the hand, and can be held with absolute security. It is expected that this improved sword-handle will be found very useful, especially by cavalry.

The Doctor's Income.—Continuing the discussion upon this subject Dr. Paget Thurston says that the trouble is not in want of patients, but in the low rates of fees. We can quite believe this, for Dr. Thurston says that in England ten per cent. of patients pay 5 shillings ($1.25), ten per cent. pay 60 cents to $1.25, while eighty per cent. pay such fees as no doctor or educated gentleman can possibly live on, the average for union, club, and dispensary patients being 10 to 15 cents.

Exhibition of Surgical Apparatus.—The Surgical Section of the International Congress of Science and Industry, which is to be held in Brussels next year, has given notice that instruments and apparatus of the following descriptions will be specially acceptable: (1) Apparatus for the treatment of spinal curvature; (2) materials for dressings; (3) gynecological instruments; (4) instruments for diseases of the urinary tract; (5) instruments for the treatment of glandular enlargements in the pharynx; (6) laryngological apparatus; (7) apparatus and dressings for antiseptic operations on the eye; (8) apparatus for the measurement of the acuteness of hearing.

Bacteriological Laboratories in Siberia and Russia.—The Medical Society of Irkutsk, the capital of Eastern Siberia, will soon have a bacteriological station in this city of forty thousand inhabitants. The Kharkov Medical Society has received from the Kürsk Government Assembly 1,500 roubles to establish a bacteriological laboratory in Kharkov, and will receive 700 roubles yearly to support the establishment.

A Mental Healing Convention was held in Boston recently, when the claims and purposes of "Christian Science" were set forth. The chief orator of the occasion was the Rev. Cyrus A. Bartol, who, according to report, spoke with beautiful and well-chosen vagueness of the general progression from the grosser to the finer, from allopathy through homœopathy to the mind cure, concluding with the old fatalistic doctrine that a man could not die until his object in life was accomplished.

English and German Throat-Doctors.—German laryngologists will be pleased to read the following from the London correspondent of the New York *Times*, who says: "I met Dr. Morell Mackenzie, who is the medical hero of the hour, shortly after his return from Berlin with his blushing honors thick upon him. There is a touch of the college professor about him and a gleam of geniality not unlike that of Oliver Wendell Holmes. The impression he made in Berlin by his cool and sensible view of the real ailment of the Crown Prince's throat, and the radical error that he pointed out in the German opinion of the case, that the disease was not a cancer, have been received here almost as a national compliment to English medical skill."

Women as Dentists.—In the Pennsylvania Dental College there are nine women enrolled this term as students. In the Philadelphia Dental College twenty-six have been graduated in the past, and in the present class there are seven enrolled and two or three others attending occasionally. The Baltimore College graduated three women and then refused further admission, nor will they to-day admit women as students.

Chicago has no Ambulances, according to the *Chicago Mail*, and recently a gentleman, taken suddenly ill, was taken home in an undertaker's coach, that being the best substitute for an ambulance at hand.

An Easy Method of Preventing Sea-sickness.—Professor William James writes to the *Boston Medical and Surgical Journal*, suggesting that by counter-irritation over the mastoid processes, sea-sickness may be prevented. He was led to this idea by his experiments with deaf-mutes, whom he found to be singularly exempt from sea-sickness. In his own case, Professor James thinks that he prevented an attack by simply using friction over the mastoid processes.

Obituary.

WOOLSEY JOHNSON, M.D.,

NEW YORK.

Health Commissioner Woolsey Johnson, M.D., died of Bright's disease at the New York Hospital, on June 21st, after a protracted illness. Since the death of his wife, two years ago, Dr. Johnson became much prostrated in health, but until within a few months manfully attended to his duties as Health Commissioner. For many years he had been attending physician to the New York Hospital. He was also a surgeon of the Eye and Ear Infirmary, and was a member of the County Medical Society, the Academy of Medicine, the Laryngological Society, and the Physicians' Aid Association. He was graduated at the College of Physicians and Surgeons in 1863. He was also a graduate of Princeton College. His age was forty-five. He became Health Commissioner in 1881, and was holding over until the appointment of his successor.

Reports of Societies.

AMERICAN ORTHOPEDIC ASSOCIATION.

First Annual Meeting, held in New York, June 15 and 16, 1887.

Wednesday, June 15th—First Day.

The Association met at the New York Academy of Medicine, and Dr. V. P. Gibney, of New York, was elected President, *pro tem.*, and Dr. Lewis Hall Sayre, of New York, Secretary, *pro tem.*

The constitution and by-laws are so framed that permanent officers are elected on the last day of each annual meeting.

The Secretary acknowledged the receipt of responses from several gentlemen concerning becoming members of the Association, and one resignation, that of Dr. Lewis A. Sayre, of New York, who believed that the Association should be a part of the Section on Surgery of the American Medical Association.

members in attendance.

Drs. Thomas G. Morton, of Philadelphia; Newton M. Shaffer, John F. Ridlon, Charles F. Stillman, of New York; A. Sydney Roberts, of Philadelphia; George B. Packard, of Hartford, Conn.; Dillon Brown and H. Ling Taylor, of New York; John C. Schapps, of Brooklyn; Henry Hodgen, of St. Louis; A. B. Judson, Samuel Ketch, C. W. Stimson, Henry W. Berg, George S. Knickerbocker, and V. P. Gibney, of New York; E. H. Bradford, of Boston; Lewis Hall Sayre, W. B. DeGarmo, and E. Develin, of New York.

congenital occlusion and dilatation of lymph-channels.

Dr. George B. Packard, of Hartford, Conn., reported a case of the above affection occurring in a child, five years of age, and involving the right lower extremity. There was no evidence of a syphilitic history. The mother was the subject of phthisis, and although the father was healthy, there was phthisis in his family. Whooping-cough was the only disease the child had had. It could walk well at the age of three years. But the difference in size between the two limbs was very apparent, and the diseased one was three-fourths of an inch the longer. The hypertrophy involved all the tissues of the limb, and partially the same side of the body. The joints and skin were apparently normal. There was some enlargement of the inguinal glands. One month ago the affected limb was three inches longer than the other, and there had been a corresponding development in size. There had never been any inflammatory condition of the skin. Dr. Gibney, of New York, saw the case in consultation; corroborated the diagnosis of congenital occlusion with dilatation of lymph-channels, and advised amputation, which was done three weeks ago, and fourteen inches removed. On examination the blood-vessels were found to be normal, the lymph-vessels enlarged, and three or four times the natural size; also the bones, the muscles, and the cellular tissue hypertrophied.

The points of interest were: (1) The increased length of the bones, and (2) the comparatively healthy condition of the skin.

Dr. H. Ling Taylor, of New York, referred to a case which he thought might possibly belong to this class. The patient was a Swedish girl, twenty years of age, whom he saw first about two years ago. The enlargement of the limb was chiefly between the ankle and knee, and the skin did not seem to be involved. The thigh and the side of the body were somewhat larger than they should be.

Dr. T. G. Morton, of Philadelphia, had seen one case in which there was marked increase in the size of the limb, and he

stretched the sciatic nerve thoroughly,

just as it emerges from the pelvis, with the result of so affecting nutrition as to diminish the size very much. He thought that this procedure might be adopted before re sorting to amputation. The first cases in which he operated in this manner were two of *elephantiasis*, several years ago. In one case he removed an inch of the sciatic nerve, and the limb diminished in size one-half, and the skin became perfectly soft. The patient died of phthisis. In the second case he divided the nerve, but would not do it in other cases, but would stretch it by preference.

Dr. N. M. Shaffer, of New York, had seen unilateral difference in the growth of bones, especially with regard to the tibia and radius, and he had often wondered as to which was the normal side. He would suggest the possibility of central origin.

Dr. Henry W. Berg, of New York, said that enlargement of the lymphatic glands in the abdomen might give rise to closure of the lymphatic ducts and thus produce

hypertrophy of the right leg.

But any interference higher up would probably give rise to hypertrophy on both sides. He believed it to be fair to presume that an adenitis could close the ducts sufficiently to produce a condition analogous to that described by Dr. Packard.

Dr. T. G. Morton, of Philadelphia, exhibited

an instrument for treatment of club-foot

in cases which do not yield to manipulation, adjustment of light apparatus, and, further on, the division of tendons and fasciæ. After the division of tendons and fasciæ the question of correcting the deformity was often a very difficult one to meet, and his apparatus was designed to give assistance. It consisted of a block of wood upon which were arranged pads, bars, and screws, by means of which the tarsus could be forced into position while the patient was under the influence of ether.

He never uses it, however, where

excision of the cuboid

can be practised. He believes that excision of the cuboid gives, in these old cases of rigid tarsus, better results than can be obtained by any other method of treatment.

Dr. J. F. Ridlon, of New York, asked if Dr. Morton had found the smaller of his instruments, for instance, sufficiently powerful to overcome the resistance offered by the internal lateral ligament, when it is shorter and stronger than normal, as it is frequently, without division of the bands.

Dr. Morton said that he used the apparatus whenever he was unable to rectify the deformity by manipulation, as, for example, some of the worst cases were those in which proper manipulation had not been practised after an operation. He would divide everything in such cases that offered resistance, then place the foot in the apparatus and force it into position, and do the whole at one operation. The dressing consisted of a tin splint, carefully padded, in which the foot was allowed to remain undisturbed, and he had not seen any untoward symptoms attend the method of treatment.

Dr. Shaffer, of New York, said that some years ago he felt very much as Dr. Morton had expressed himself concerning the inveterate character of a certain number of cases of club-foot, where the foot is tender and the tissues sensitive, etc. In the majority of these cases, however, where most surgeons would operate at once, he had been able to effect complete

cure by means of traction.

Not that every case could be cured by traction, but that many which have been condemned to osteotomy or tarsot-

omy, he had seen yield to it. What he would claim for traction is that the loss of time in treatment is compensated for by the *symmetrical feet* obtained as the result. He was ready to perform tenotomy or osteotomy when antero-posterior and lateral traction failed.

Dr. Morton would not use his forcing instruments in children under six or seven years of age. He referred more especially to the use of the instrument in young subjects, as an aid to the hand. In the adult subject, with a dense, unyielding foot, he had regarded it as absolutely impossible to give any benefit without the use of force, and by means of his large apparatus he had been able to materially shorten the duration of treatment.

Dr. Lewis Hall Sayre, of New York, exhibited a patient on whom he had divided the tendo-Achillis and the plantar fascia in

A CASE WHICH HAD RESISTED MECHANICAL TREATMENT.

The case was one of talipes following infantile paralysis, and the operation was performed two weeks ago. The dressings were removed, and the foot was found in excellent position.

Dr. Ketch, of New York, while he recognized the good result obtained by operative treatment, entered his protest against the case being reported as one in which mechanical treatment had failed; for, one year ago he applied Shaffer's extension and traction shoe, with tenotomy reserved as a further measure if necessary; saw the patient twice only, and had not seen him since. Practically he had found that treatment by traction could not be trusted to parents, and he thought it unfair to bring the case forward as one illustrating the inefficiency of mechanical treatment. He was quite confident that the heel could have been brought down without tenotomy.

Dr. Ridlon asked Dr. Sayre if he was satisfied with the result of bringing the flexion to a right angle.

Dr. Savre said he was satisfied with the result thus far obtained, but that treatment must be continued to carry flexion as far beyond a right angle as might be, and then watch the case to see that the deformity does not return.

Dr. H. Ling Taylor suggested the appointment of a committee to investigate and report on the subject of "point pressure" and division of contractured tissues.

Dr. A. Sydney Roberts, of Philadelphia, thought that more permanent results could be obtained by extension and traction than by division of tendons and fasciæ. He cited a case in which positive relapse occurred after an apparent cure by operative procedure.

Dr. C. F. Stillman, of New York, believed it to be important in almost every case to put the patient through a course of

PREPARATORY TREATMENT,

consisting of rest in bed, perhaps, for some weeks, with the application of thick poultices, which would greatly increase the pliability of the tissues and facilitate operative measures and after-treatment. He regarded *after-treatment* as the most important of all, for upon its thorough application depended the completeness of the cure. To accomplish the last satisfactorily, some kind of mechanical appliance was almost always necessary.

The discussion was continued by Drs. Morton, of Philadelphia, and Stillman, Shaffer, and Berg, of New York.

Dr. V. P. Gibney, of New York, presented two patients illustrating

OSTITIS OF THE SHOULDER,

attended by false anchylosis. In the first case the arm in 1881 was one inch smaller than the well limb, and in 1884 one inch and a half. There still remains some atrophy, but during the past year the arm had increased in size and was quite useful.

In the second case there was marked atrophic changes, but improvement had taken place after *brisement forcé*, which also had been practised more than once in the first case.

Dr. Ridlon, of New York, cited a case which led him to the belief that recovery may take place in some of these cases under the thorough use of mercury.

Dr. H. Ling Taylor, of New York, reported a case of

POTT'S DISEASE, WITH AN UNUSUAL DEFORMITY,

mainly lateral, from the beginning, with two knuckles in the spine, one at the eleventh dorsal, and the other at the third or fourth lumbar vertebræ. The points of interest in the case were the extreme lateral distortion, with angular curvature at two points, and the prompt rectification by means of the antero-posterior splint.

Dr. Ridlon, of New York, had had a similar case, which he treated successfully by means of the antero-posterior support combined with the plaster of Paris.

Dr. Ketch, of New York, thought that lateral deviation was not uncommon, and in the early stages of the disease he thought that it might be expected almost always, especially when the lower part of the spine was affected.

Dr. Shaffer, of New York, had regarded extreme lateral deviation as one of the best guides in diagnosis of Pott's disease low down.

Dr. Stillman, of New York, mentioned a case that confirmed Dr. Shaffer's statement.

Dr. Henry Hodgen, of St. Louis, referred to a case which illustrated the principle in Dr. Taylor's case, and it was the only one which he had seen where there was any recession of the deformity.

Dr. A. B. Judson, of New York, exhibited an

ISCHIATIC CRUTCH,

the description and illustration of which appears in full in The Medical Record, page 721.

Dr. T. G. Morton, of Philadelphia, then made some remarks with reference to

ANCHYLOSIS OF THE KNEE,

whether osseous or where there was a slight amount of motion. The point in treatment to which he directed special attention was *suturing the femur and the tibia* with the largest catgut, after removing the wedge-shaped portion of bone corresponding to the angle of the deformity. In three cases he had secured immediate union of the soft parts and of the bones without separation or suppuration. The suturing obviates the use of any lateral support. The safest dressing is a plaster-of-Paris posterior splint, fairly moulded to the limb, and a retentive bandage.

The communication was discussed by Drs. Shaffer, Ketch, and Stillman, of New York.

The Association was entertained at the Casino in the evening.

Thursday, June 16th—Second Day.

The first order of business was the discussion on Dr. Judson's *ischiatic crutch*, which was participated in by Drs. Gibney and Stillman, of New York, and Dr. Roberts, of Philadelphia, all speaking in commendation of the instrument.

Dr. A. Sydney Roberts, of Philadelphia, exhibited

A PLANTAR SPRING FOR FLAT FOOT.

It was a modification of the old Knight spring, the modification consisting in slitting the edges of the inner curve. The spring is designed to counteract the inward rotation of the inner arch of the foot in walking. The condition to be overcome in these cases is the breaking down of the inner arch of the foot with rotation.

Dr. Ketch, of New York, spoke of the advantages of the modified spring presented by Dr. Roberts, as he had used it in a number of cases.

Dr. Shaffer, of New York, spoke of *shortening of the gastrocnemius muscle* as an etiological factor in flat foot.

Dr. L. H. Sayre, of New York, thought that shortening of the gastrocnemius might be an important factor.

Dr. Ketch was unable to understand how such shortening could beget flat foot.

The discussion was continued by Drs. A. B. Judson, of New York, Roberts, of Philadelphia, Shaffer, Stillman, and Gibney, of New York.

Dr. Bradford, of Boston, in behalf of Dr. Lovett, of Boston, presented a specimen, with its history, from

A CASE OF HIP DISEASE, IN WHICH IT WAS SUPPOSED THAT A VERY GOOD RECOVERY HAD TAKEN PLACE.

The patient died of tetanus. There were found caries of the acetabulum, with a sequestrum pointing inward. The head of the femur was solidified, and enabled the boy to walk with a stiff joint. On the top of the femur was a small loose sequestrum.

Dr. Lewis Hall Sayre, of New York, presented a somewhat similar specimen removed by excision. These specimens gave rise to a protracted discussion on the question of excision of the hip.

The President, in behalf of Dr. Ap Morgan Vance, of Louisville, Ky., presented what looked very much like the

"CONNECTING LINK."

It was a tail-like body removed from the side of the coccyx of a mulatto girl three years old. The mother was an octoroon seventeen years of age, and the father three-fourths white and eighteen years old. There was no power of movement in this caudal appendage fully four inches long, nor bone nor muscle.

Dr. John F. Ridlon, of New York, gave the notes of two cases of

POTT'S DISEASE THAT ILLUSTRATED THE DIFFICULTY OF DIAGNOSIS IN CHILDREN.

In very young children, caries of the vertebræ up to the third or fourth dorsal may give rise to symptoms referable only to the neck.

The communication was discussed by Dr. Ketch, of New York.

Dr. Henry Hodgen, of St. Louis, then opened the discussion on

THE TREATMENT OF PSOAS ABSCESS FROM CARIES OF THE SPINE.

The treatment which he, in conjunction with Dr. Mudd, of St. Louis, had adopted in five cases with good results was early and repeated aspiration. He did not claim that it was an absolute cure for all cases, but that they might be arrested after from two to five aspirations. He would not repeat aspiration more than six or seven times, but would use the needle as soon as he could diagnosticate the presence of pus.

Dr. Shaffer, of New York, had been unable to empty these abscesses with the aspirator. He would prefer, could he direct, to have them all open into the rectum. He had known several to open into the bladder with good result.

Dr. Ridlon, of New York, had seen several abscesses connected with caries of the lumbar vertebræ disappear spontaneously.

Dr. Ketch, of New York, spoke of the advantages of the non-interference plan of management.

Dr. Hodgen disbelieved entirely in the expectant method of treatment.

Dr. H. Ling Taylor, of New York, exhibited the

ANTERO-POSTERIOR SPINAL SUPPORT,

and pointed out the modifications which it had received somewhat recently.

He also exhibited an

ABDUCTION CRUTCH

designed to overcome adduction, either in hip disease or in old cases of dislocation.

Dr. Ketch, of New York, exhibited

A DEVICE FOR OVERCOMING INTERMITTENT TRACTION IN HIP-JOINT APPARATUS

due to bagging of the straps in the old hip-splint.

Dr. Charles F. Stillman, of New York, exhibited an apparatus for the treatment of

ROUND SHOULDERS

in which was illustrated the action of the new V-lever principle.

Dr. Dillon Brown, of New York, presented a little patient upon whose tibia he had performed

OSTEOCLASIS.

It was one of fifteen cases in which he had operated successfully, with return of the deformity in only one case.

Dr. Bradford, of Boston, reported five cases in which he had performed

KOENIG'S OPERATION OF LUMBAR AND ILIAC INCISION FOR ILIAC ABSCESS

with good results. One was a case of double iliac abscess.

Dr. Shaffer, of New York, had seen iliac abscess become incapsulated in many cases and then give rise to no inconvenience whatever.

Dr. Bradford thought that the inability to say whether or no the abscess contained sequestræ rendered the expectant plan of treatment especially dangerous.

Dr. Bradford also reported a case of

TORTICOLLIS FROM DEFECTIVE ATTACHMENT OF THE MUSCLES OF THE EYE.

In order to get binocular vision it was necessary for the boy to put his head in the position of torticollis.

Dr. S. Knickerbocker, of New York, described an apparatus which he had devised for preventing

ADDUCTION IN HIP DISEASE

while the case was under treatment.

The Society then went into executive session. The following officers were elected for the ensuing year :

President—Newton M. Shaffer, of New York.

Vice Presidents—E. H. Bradford, of Boston, and A. Sydney Roberts, of Philadelphia.

Secretary and Treasurer—Lewis Hall Sayre, of New York.

Corresponding Secretary—S. Ketch, of New York.

The Committee on Organization, Drs. Shaffer, Gibney, and Sayre, entertained the Association and guests with a banquet at the St. Nicholas Club in the evening.

Perforation of the Bladder.—Drs. Benham and Greig Smith record in the *Glasgow Medical Journal* the case of an imbecile who pushed the whalebone of an umbrella up his urethra and into his bladder. Two years afterward, during an autopsy, the man having died of Bright's disease, the whalebone was found to have perforated the bladder and passed into the peritoneal cavity, one end still, however, remaining in the bladder, and on this extremity a phosphatic calculus. During life the patient never complained of any vesical or abdominal trouble.—*Medical Press.*

Warm Ether as an Anæsthetic.—Dr. M. W. Hobbes advocates, in the Cincinnati *Lancet-Clinic*, the advantage of warming ether previous to its administration in the production of anæsthesia. He and Dr. Taylor have tried the method in upward of thirty cases, and he writes that the patients not only came under the influence of the drug more readily, but they also recovered more rapidly and pleasantly from the anæsthesia than patients generally do who have been brought under its influence in the ordinary way of administering ether cold.

New Instruments.

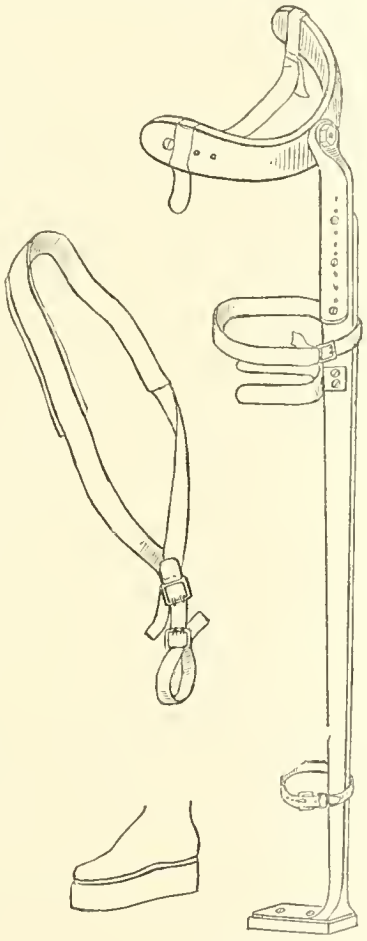
THE ISCHIATIC CRUTCH.

By A. B. JUDSON, M.D.,

NEW YORK.

This apparatus is for use in the treatment of deformities and diseases of the joints of the lower extremities. By converting the affected limb into a pendent member it removes from it the weight of the body in standing and walking. This is not a new idea in surgery,[1] but the importance of the subject leads me to describe in detail an instrument which an experience of two years has shown to be easily adjusted, conveniently worn, and, with the aid of a high sole on the well foot, entirely competent to keep the weight of the body from falling on the affected limb when the patient is up and active.

The frequent occurrence of hip disease and white swelling of the knee, and the rarity of a similar condition in the shoulder and elbow, would support the theory of the traumatic etiology of joint-diseases, if it were not for the fact that the primary lesion in articular osteitis is a central focus which could hardly be produced by traumatism. It is not improbable, therefore, that the comparative exemption of the upper extremity from destructive joint-disease is to be explained by the supposition that a focus in the cancellous tissue may undergo spontaneous resolution when exempt from disturbance in a pendent member, and may be expected to become progressive when exposed to the violence which habitually assaults the bony tissue of the lower extremity.



In the orthopædic institutions of this city, as shown in their annual reports, cases of disease of the larger joints were treated in 1885 in the following numbers: Hip, 564; knee, 258; shoulder, 9; elbow, 10. It may be said that cases involving the shoulder and elbow are more likely to seek relief in general rather than in orthopædic charities. Notwithstanding this, and perhaps other reasons, for discrediting the apparent force of these figures, it is believed that they represent a fact of practical importance, from which the inference is fairly drawn that in certain cases of osteitis of the hip and knee the persistent use of the ischiatic crutch, from the early incipiency of the disease, would lead to recovery before the appearance of the severer symptoms. Indeed, in those cases of incipient hip disease which recover with unimpaired symmetry and function under treatment by the hip-splint, it is impossible to say whether the good result is due to the use of the splint as an apparatus for applying traction or to its use as a crutch, for the hip-splint, with its rack and pinion and adhesive plaster, is as truly an ischiatic crutch as the simpler apparatus here described, provided its upright and pelvic bands are sufficiently inflexible to keep the weight of the patient from bringing his heel to the ground.

The ischiatic crutch is represented in the figure, which requires but a few words of description. The perineal strap, which is a bit of Allien's webbing covered with blanketing and canton flannel, has a loop at each end, which passes over the screw by which it is kept in place. By loosening the nut the pelvic band, which has the outline of a semi-circular arch on low piers, may be adjusted at the desired angle with the upright, where it should be fixed by tightening the nut. The head of the screw-bolt is counter-sunk, and the screw-holes, of which there are three at each end of the band for the proper adjustment of the perineal strap, are "upset" by a few blows with a riveting hammer on the inner surface of the steel band before it is covered with hard rubber. The **U**-shaped steel-piece and the webbing retentive strap find their proper place a short distance above the knee, while the leather strap is loosely buckled above the ankle. The patient's head and the arm of the affected side pass through the large loop of the shoulder-strap, while the upright passes through the small loop which comes up on the inner side of the pelvic band. This part of the apparatus is to be so adjusted that when the splint is raised in walking its weight is felt on the opposite shoulder. The upright is shod with sole-leather. Its length is readily altered, and the perineal strap should be of such a length as to make the pelvic band fall on a level midway between the anterior iliac spine and the great trochanter.

In a case presented before the Surgical Section of the New York Academy of Medicine on May 9, 1887, the patient was a boy, ten years of age, in whom the left knee had been the seat of chronic osteitis for a year and a half. Since the application of the crutch in December, 1886, the disease has been quiescent, and probably progressing toward recovery. The boy is 4 feet 2 inches in height, and weighs 51 pounds without the splint. The apparatus complete weighs $2\frac{3}{4}$ pounds. The pelvic band is 6 inches in diameter, and is made of a steel bar $\frac{3}{16} \times \frac{14}{16} \times 12$ inches, covered with hard rubber. The perineal strap is 9 inches long. The bars composing the upright are $1 \times \frac{3}{16}$ inch. The upright as worn is $28\frac{1}{2}$ inches in length, and the distance from the pelvic band to the knee-piece is 9 inches. The high sole is $2\frac{1}{2}$ inches thick. The cost of the steel, finished with great care and electro-plated, and the hard-rubber work was $14.25. This expense could be materially reduced at the sacrifice of elegance, without impairing the efficiency of the apparatus, and, with less nicety in construction and at the sacrifice of some convenience on the part of both the surgeon and the patient, the cost could be reduced to but little more than a nominal sum. The boy has attended school without interruption since its application, and from the first has walked, without a complaint and with evident convenience, from his home to the out-patient department of the hospital, a distance of one and three-fourths of a mile. He removes the crutch at night.

I first used this form of apparatus in convalescing cases of hip disease, when traction and fixation were no longer required. In the treatment of white swelling of the knee it has conveniently taken the place of Thomas' splint, and is to be worn only when the patient is out of bed, fixation of the joint being maintained by an independent splint which is constantly worn. In both of these classes of cases the results have been entirely satisfactory. The ischiatic crutch would doubtless be useful in the treatment of disease of the ankle-joint and ununited fracture of the shaft of the femur and, probably, in fracture of the femoral neck, as well as in cases of osteitis of the lower extremities not directly associated with a joint. In cases of resistant club-foot the removal of

[1] See a paper on The Question of Axillary or Ischiatic Support in the Treatment of Joint-diseases of the Lower Extremity, MEDICAL RECORD, pp. 1–3, July 2, 1882.

the weight of the body from the affected foot by the use of this apparatus, during certain stages of the treatment, would obviously facilitate reduction.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 12 to June 18, 1887.

Baxter, J. H., Colonel and Chief Medical Purveyor. To proceed to New York City for the purpose of inspecting the medical purveying depot at that place. S. O. 133, A. G. O., June 10. 1887.

Alden, Charles H., Major and Surgeon. Par. 15, S. O. 52, A. G. O., March 5, 1887, is so amended by Par. 9, S. O. 133, A. G. O., June 10. 1887, as to direct that he be relieved from duty in Department of Dakota about June 20, 1887, and he is granted leave of absence from the date when so relieved to include August 27, 1887.

Fryer, B. E., Major and Surgeon. Found incapacitated for active service by an Army Retiring Board, and granted leave of absence until further orders on account of disability. S. O. 133, A. G. O., June 10, 1887.

Hall, John D., Captain and Assistant Surgeon. Leave of absence extended one month. S. O. 136, A. G. O., June 14, 1887.

Borden, W. C., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. S. O. 138, A. G. O., June 16, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending June 18, 1887.

Walton, Thomas C., Surgeon. Ordered, June 15th, for examination preliminary to promotion as Medical Inspector.

Price, A. F., Surgeon. Detached from special duty at Annapolis, Md., to proceed home and await orders.

Flint, James M., Surgeon. Detached from the Albatross, and ordered to the Smithsonian Institution.

Willson, W. G. G., Passed Assistant Surgeon. Ordered to the Receiving-ship Independence, Mare Island, Cal.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 18, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	5
Scarlet fever	60	15
Cerebro-spinal meningitis	7	8
Measles	39	4
Diphtheria	116	35
Small-pox	4	2
Yellow fever	0	0

Treatment of Œdema of Lungs.—Nothnagel, in a clinic published in the *Wiener Med. Zeitung*, advises as follows: First, to stimulate the heart. If the patient be conscious and can swallow he gives the stimulants which act most quickly, viz., the champagne wines. Champagne is the most rapid and the surest in its excitant action of all the wines. Quincke years ago showed that alcohol is more quickly absorbed when it is introduced into the stomach along with carbonic acid. Or he gives strong black coffee with, as a rule, some brandy, rum, or arrack; or else a few drops of sulphuric ether. If the patient cannot swallow he resorts to hypodermic injection, preferring camphor to sulphuric ether. In giving large doses of ether you are apt to lose its primary exciting action in its stupefying effect; in proof of this he gives the result of three hundred and sixty-six injections of ether in rabbits, which as completely narcotized them as if the ether had been inspired. He injects one centigramme of camphor dissolved in oil (one in ten) and repeats this two, four, or five times in quick succession. Second, to limit the transudations of fluid from the vessels into the lung tissue and bronchi. For this purpose, Nothnagel only knows of one treatment, the one originated by Traube. This consists in administering five centigrammes of acetate of lead as a powder every quarter or half hour for four or five doses. As the symptoms abate it should be given every one or two hours. The next best thing is a large blister reaching from one nipple to the other, and from the manubrium to the ziphoid cartilage, the irritation of the skin thus produced probably causing contraction of the lung-vessels.

Case of Poisoning by Artemidis Nephrosis.—Dr. William J. Wonder, of Little Muddy, Dak. Ter., reports the following case of supposed poisoning by *artemidis:* The query might be raised if the child were not simply suffering from eclampsia, the result of gastric irritation. J. R——, seven years of age, on October 17, 1886, was seen by his mother to be eating some green leaves, which afterward proved to belong to the above-mentioned plant. Three hours afterward I was sent for and found him in convulsions and perfectly unconscious. From the history of the case I thought at once that it was one of vegetable poisoning, and proceeded to administer an enema of castor-oil and an emetic of *human urine*, no other emetic being available in this out-of-the-way place. Both acted in about twenty minutes, and the floor was green with the double evacuations. The child soon regained consciousness, and, although weak, recovered in about three hours under the administration of the following remedy, which I can recommend under similar circumstances:

℞. Aq. menth. pip.,
Syr. simp .....āā f ℥ ss.
Spts. vini. gallici ..... f ℥ ij.
Sig.—Tablespoonful every hour.

I think the prompt use of an emetic, although one so repugnant to the feelings, was really the cause of the child's recovery. If there are any other recorded cases of poisoning by this plant I would be glad to hear of them through the columns of your valued paper.

The Treatment of Compound Fractures by Professor Max Schede, of Hamburg, presents some novel features, according to a correspondent of the *Cincinnati Lancet and Clinic*. The wound or wounds are laid freely open, irrigated thoroughly with corros. sublimat. sol., 1–1,000, all loose splinters of bone removed, fracture reduced, and fixation of the fragments secured by means of a little device of Dr. Hansmann, the first assistant surgeon. It consists of a little metal plate about half an inch wide and as long as is necessary, perforated with holes at short distances. It is laid upon the periosteum, and a screw inserted through one of the holes into the bone on each side of the point of fracture. Two of these little splints are usually employed in a fracture of a large bone, after which the immobility of the limb is secured in the usual way by splints; the wound being left open and treated antiseptically. The metal plate has the advantage over bone sutures in being much more easy and simple in its application as well as removal, and it secures and maintains the approximation and fixation of the fragments just as firmly.

Bougie, the filiform, 139.
Bowditch, Professor Henry I., 441.
Boy, a double-headed, 550.
Boyd, Dr. B. H., insolubility of capsules, 268.
Brain, abscess of, 332; localization of disease of, 552; cyst of, 535; gummy tumor of, 353; pistol-shot wound of, 445; sarcoma of, 10, 534.
Brandt, Dr. J. R., Bergeon's method of treating of phthisis, 710.
Brass-workers' disease, 689.
Bread, 701.
Breasts, amputation of, under cocaine, 634.
Breath, bad, 559.
Bridgwater, Dr. S., easy labor, 12.
Bright's disease, 564; without albuminuria, 393.
British Medical Association, time of holding meeting in 1887, 331.
Bronchitis, affected by sleep, 354; asthmatic, 607; in children, 165.
Broncho-pneumonia, 513; quinine in, 222, 283.
Bronchus, catheterization of, 330.
Brothers, Dr. A., early dentition, 268; poisoning from eggs, 545.
Brown, Dr. Daniel, placenta prævia, 435.
Brown, Dr. Dillon, dangers of intubation, 705.
Brown, Dr. S. A., expert witnesses, 169.
Browning, Dr. William, pressure-paralysis of the radial nerve, 435.
Brunton, Dr. T. Lauder, book notice, 274.
Brush, Dr. E. F., mammary gland, 351.
Bryant, Dr. Joseph D., notice of book by, 472.
Bubo, endemic, idiopathic, 112.
Buck, Dr. A. H., chronic inflammation of the middle ear, 1.
Bundy, Dr. A. D., family epidemic of typhoid fever, 353.
Burdett, Henry C., Esq., hospitals, etc., 199.
Burns, 518; adhesions from, 546.
Butter, test for, 295.
Buxton, Dr. Dudley, influence of certain salts on the muscles, 481.

C

Cæsarean section, for fibromyomata, 390; the first in the West, 101.
Caillé, Dr. A., intubation of the larynx, 324, 687.
Calculi, intestinal, 123; vesical, 589, 657; urethral, 194; urinary, microbes in, 28.
Camphor, poisoning by, 125.
Cancer, alveloz in, 669; Chian turpentine in, 28; curability of, by operation, 85, 105; method of arresting, 659; of the

uterus, 107, 161, 363; primary, of the lungs and bronchial glands, 269; relation of, to nervous depression, 255.
Capsules, giving medicines in, 84; insolubility of, in an inflamed stomach, 268.
Carcinoma, epithelial origin of, 195; of both ovaries, 365; of the spine, 195; of the uterus, 437.
Carhart, Dr. J. W., "grass staggers," 10.
Caries, vertebral, 171, 361.
Carlsbad waters, 382.
Carpenter, Dr. James S., fracture of the skull, 544.
Carr, Dr. W. L., dispensary abuse, 225.
Cassidy, Dr. J. J., secondary syphilitic inoculation or contagion, 125.
Cataphoresis, in neuralgia, 552.
Catarrh, cervical, 394; nasal, Hager's remedy for, 423; remedy, Arabian, 479.
Catheter, double-barrelled, 608.
Catheterization of trachea and bronchus, 330.
Catramine, 387.
Cauldwell, Dr. Charles M., antifebrin in phthisis, 426.
Centenarians, diet of, 312.
Cerebellum, cystic sarcoma of, 364; pathology of, 281.
Cerebrum, localized lesions in, 694.
Cervix uteri, laceration of, 448.
Chancroid, 615; and salicylic acid, 200; supposed virus of, 276.
Chapin, Dr. Amory, cocaine in coryza, 70.
Chapin, Dr. Henry Dwight, peripheral neuritis, 57.
Charcot's joint disease, 297.
Cheesman, Dr. William S., acetonæmia, 433.
Chew, Dr. S. C., strophanthus, 515.
Childbirth, mortality from, 255, 256.
Chin, the data of, 254.
Chloral eruption, 563.
Chlorodynomania, 395.
Chloroform, 312, 453, 458, 473; in labor, 156.
Chlorosis, pulverized spleen in, 383; sulphur in, 265.
Cholectomy, 303.
Cholera, in Chili, 507; in Japan, 225; in Valencia, 394; new fungus, 242.
Chorea, 226, 357, 608.
Cicatrices, hyperplastic, 280.
Cimicifuga in chorea, 226.
Circumcision, tuberculosis from, 355; under cocaine, 12, 114.
Cirrhosis of the liver in children, 664.
Citro-chloride of iron, 255.
Classification of mental diseases, 674.
Clavicle, fracture of, 76.
Clothing, warm, 73.
Club-foot, 193.
Coan, D. T. Munson, mineral waters, 38, 49.
Cocaine, 17, 200; an overdose, 13; exaggerated dangers of, 635; in acute gastritis, 296; in circumcision, 114, 255; in coryza, 70; herniotomy under, 124; peculiar effect of, 325; the third scourge of humanity, 56.
Cod-liver oil, in nervous affections of children, 394; purity of, 395.
Coffee, action of, 437.
Cold, application of, to the præcordia in fever, 43.
Colds, sure cure for, 359; taken in cars, 687.
College of Physicians and Surgeons, Philadelphia, centennial of, 47.
Collie, Dr. Alexander, book notice, 443.
Collins, Dr. J. W., can diphtheria be communicated by tooth-forceps? 268.
Collodion, antiseptic, 424; new, 368.
Colon, dilatation of, 96.
Color-blindness in Alabama, 416.
Coma, nature of, 713.
Conjunctivitis, acute muco-purulent, 135; microbes of acute catarrhal, 571.
Connecticut State Medical Society, 689.
Constipation, 140, 270, 296; infantile, 536.
Consumption, and Colorado, 154; East Indian cure for, 368; is it on the decrease? 219.
Consumptives, soothing for, 563, 620.
Contagion, nervous, 188.
Convulsions, from impacted fæces, 241; uræmic, morphine in, 530.
Copeland, Dr. W. P., adhesions following burns, 546; burns, 518.
Cord, spinal, sarcoma of, 10; scleroses of, 249.
Corn silk in cystitis, 226.
Corning, Dr. J. Leonard, new mode of producing neural anæsthesia, 319.
Corrigan's pulse, 325.
Coryza, cocaine in, 70.
Cough, nocturnal, in children, 188.
Count Tolstoi on physicians, 74.
Country doctor and hard thinking, 83.
Cranium, fracture of the base of the, 189.
Creasote in phthisis, 526.
Creatinin in normal urine, 411.
Cremation, 217; in Denmark, 189.
Crime and monomaniacal infatuation, 658.
Crotalus, 394.
Crown Prince's malady, 689.
Cuboid, excision of, 718.
Curette and double catheter, 169.
Curtis, Dr. H. Holbrook, treatment of the upper air-passages, 493.
Curtis, Dr. Romaine J., long beards, etc., 136.
Cystitis, corn-silk in the treatment of, 226; gonorrhœal, 267, 600.
Cystotomy, 615.

D

Dabney, Dr. William C., nitro-glycerine and epilepsy, 450.
Dakota doctor, 674.
Davis, Dr. N. S., testimonial to, 155.
DeGarmo, Dr. W. B., treatment of hernia by subcutaneous injections, 35.
Deaf-mutes, 356.
Death, a sign of, 55.
Deformities, congenital, influence of maternal impressions on, 4.
Delafield, Dr. Francis, acute and fatal tuberculosis of the lymphatic glands, 425.
Delavan, Dr. D. Bryson, erysipelas of the upper air-passages, 464.
Dellenbaugh, Dr. Z. T., antipyrin in dysmenorrhœa, 579.
Democracy, a cause of financial depression among physicians, 74.
Denhard, Dr. Charles E., modification of O'Dwyer's gag, 479.
Dentition, early, 127, 268, 495.
Dentifrice, 340.
Dermatitis herpetiformis, 380.
Diabetes, 414; and syphilis, 580; in childhood, 227; Martineau's remedy, 525, 536, 583; phosphatic, 196, 712.
Diagnosis, help to teaching physical, 187.
Diarrhœa, 355; and antiseptics, 132; antiseptic treatment of summer, 77; summer, 331.
Diarrhœal diseases, 240.
Diddier, Jeremy, dispensary, 19.
Digestibility of the albuminoids, 436.
Digitaline in France and Germany, 643.
Diphtheria, 45, 75, 580; and tooth forceps, 268; bichloride in, 265; cauterization in, 507; hospital, proposed, 470; local treatment, 397, 402, 417, 432, 465, 506, 562, 635.
Diseases, registration of contagious, 384.
Disinfectants, 526.
Disinfecting the alimentary tract, 442.
Dispensaries and out-patient departments, 73.
Dispensary, abuse, 225; for the little toe, 19.
Dissection, preservation of subjects for, 302.
Doctor, a country, a hundred years ago, 337; average income of the family, 524; printing of the title of, 55, 443; the country, and hard thinking, 225.
Doctors, excessive supply of, 385; plethora of, 340.
Doctor's horse, 298.
Dog, musical discrimination of a, 112.
Douche, vaginal, 381.
Douches, fatal poisoning from two vaginal, 563.
Drunkards, autopsies on, 508.
Duhring, Dr. L. A., dermatitis herpetiformis, 380.
Dujardin-Beaumetz, Dr., book notice, 274.
Dwelling-houses, air of, 689.
Dying, at the ebb of the tide, 713; transferral of the, 550.
Dysmenorrhœa, antipyrin in, 579.
Dyspnœa, paroxysmal cardiac, 159.

E

Ear, chronic catarrhal inflammation of the middle, 1; diseases of, 395; injury of, caused by the bursting of a shell, 201; multiple paracentesis, 157; quacking sounds in, 368; suppuration in the brain following disease of, 404.
Ears, boxing the, 649.
Earle, Dr. Pliny, book notice, 104.
Ebstein on gout, book notice, 104.
Eclampsia, puerperal, 69, 189.
Eczema, 567, 617; rubrum, 708.
Edgar, Dr. J. C., physical diagnosis, 187.
Edson, Dr. Benjamin, gummy tumor of the brain, 353; quinine in broncho-pneumonia, 283.
Eichhorst, Dr. Hermann, book notice, 274.
Einhorn, Dr. Max, fermentation test for sugar in the urine, 91.
Elastic fibres, new method of staining, 361.
Electricity in diseases of the genito-urinary organs, 411; in the treatment of epilepsy, 334.
Electrolysis and cystic tumors of the ovary, 380.
Electro-therapeutics, 243.
Elliot, Dr. George T., ichthyol, 321.
Elliott, Dr. George R., antifebrin in typhoid fever, 8, 253.
Ellis, Dr. H. L., tedious labor from relaxed abdominal walls, 325.
Ely, Dr. A. G., death notice, 416.
Embalming, antiquity of, 477.
Embolism, cerebral, 529.
Emmet, Dr. Thomas Addis, ether and nephritis, 199.
Emigrants' Hospital, 46.
Empyema in children, 602, 604, 606, 634; surgical operation for, 420, 613.
Encyclopædia of surgery, book notice, 104.
Enteroptosis, 217.
Epicondyle, fracture of the inner, 241, 435.
Epididymitis, syphilitic, 194, 617.
Epilepsy, 228, 333, 334, 390; cortical, with temporary aphasia, 280; nitro-glycerine in, 450.
Epileptic colony at Bielefeld, 463.
Epiphysitis, acute, of the hip, 264, 277.
Epistaxis, 519.
Epithelioma of the auricle, 124.
Erysipelas, 340, 393; facial—is it contagious? 366; of the upper air-passages, 464.
Ether, 453, 458, 473; and nephritis, 199; contra-indications to its use, 52; in nephritis, 254; in nephritis and Bright's disease, 122; warm, as an anæsthetic, 720.
Eye, effect of excessive illumination on, 216; foreign body in, 362; insufficiency of the superior rectus muscle, 462.
Eyelids, Corning's method of local anæsthesia for operations on, 263.
Experts, compensation of, 584, 611
Exsection of the hip, 586.

F

Face, progressive hemiatrophy of, 428.
Fagge, Dr. Charles Hilton, book notice, 103.
Faith-cures, 302, 523.
Farnam, Dr. George Bronson, notice of death of, 47.
Fasting, 415, 526.
Fat and sugar, 674.
Fatty degeneration, acute, of the new-born, 171.
Feet, 610.
Felon, how to abort, 123.
Femur, exsection of the head of, 446.
Féré, Dr., book notice, 274.
Fermentation as a test for sugar in the urine, 91.
Fever, 468; antipyretic treatment of, 665; cold applications to the præcordia in,

43; nature of, 497; cerebro-spinal, 542, 555; malignant, immediate cause of death in cases of, 437; scarlet, 70, 415; typhoid, 295, 396, 554, 695; and contagion, 579; antifebrin in, 8; antipyretics in, 49, 666; bacillus, effect of freezing on, 345; baths in, 620; family epidemic, 353; inhalation of cold air in, 190; microbe of, 470; mortality of, 326; pilocarpin in, 393; relation between it and drinking-water, 429, 525; simulating cerebro-spinal meningitis, 251.
Fibroma of the lower jaw, 21.
Fibro-sarcoma, parovarian, 21.
Fingers, a six-fingered family, 592; amputation of, under cocaine, 268; supernumerary among negroes, 172.
Finley, Dr. Mary J., poisoning by camphor, 125.
Fisher, Dr. W. C., circumcision under cocaine, 12.
Fistula, urethro-vesical vaginal, 676.
Flat-foot, 719.
Flint, the late Dr. Austin, memorial tablet, 360.
Flood, Dr. Henry, artificial leech, 339.
Folsom, Dr. Charles F., book notice, 273.
Foods, digestibility of the different nitrogenous, 128.
Fothergill, Dr. J. Milner, book notice, 275.
Fracture, multiple, 241; of the base of the cranium, 189; of the skull, 544, 710.
Fruitnight, Dr. J. Henry, local treatment of diphtheria, 635.
Fractures, compound, 722.
Fuchs, Dr. Albert F., herniotomy under cocaine, 124.

G

Gage, Dr. S. H., embalming, 477.
Galazima, 56.
Galezowski, Dr., notice of book by, 103.
Gall-stones, 420; encysted, laparotomy for, 22; multiple and retained, 446; very large and very small, 107.
Galt, Dr. F. J., book notice, 444.
Galvanic current, dosage of, 630.
Gangrene, gaseous, 640.
Garlic, in painful hemorrhoids, 434.
Gastric tubules, atrophy of, 694
Gastro-ectasis, functional, 440.
Gangrene of the intestine, 389.
Gas, danger of water, 132.
Gastritis, acute, cocaine in, 296.
German Congress for internal medicine, 527, 552.
Gerster, Dr. Arpad G., ether and chloroform, 453, 473.
Gibney, Dr. V. P., epiphysitis of the hip, 264.
Gilmore, Dr. A. P., irido-cyclitis, 127.
Goître, 702.
Goldsmith, the Middleton lectures, 101, 154, 173.
Gonococcus in arthritis, 407.
Gonorrhœa, 505, 545; and strictures, 140; internal treatment of, 97.
Gout, 382; brought on by starvation, 76; of the heart (?), 531.
Grant, Dr. J. A. S., Bey, diphtheria treated with corrosive sublimate, 265.
Granuloma fungoides, 71.
"Grass Staggers," 10, 130.
Griffin, Dr. Edward D., notice of death of, 611.
Gunn, Dr. R. A., book notice, 443.

H

Hæmaturia, 390.
Hæmophilia, congenital, 208.
Hæmoglobinæmia, 355.
Hæmoglobinuria, malarial, 140.
Hance, Dr. Irwin A., tracheotomy after intubation, 707.
Hand, plastic operation for deformity of, 294.
Hands, art of washing, 172.
Handbook of medical sciences, notice, 471.
Hay-fever, 647.
Haynes, Dr. S., influence of position on the progress of labor, 95.
Headache, cold affusion in, 393; congestive, 671.
Healing, the Christian science of, 155.
Heart, cause of the rhythmical contraction of, 581; clinical significance of endo-cardial murmurs, 160; deformities of, 445; disease of, and active work, 154; effect of high altitude on disease of, 171, 697; fatty, 16; gout (?) of, 531; influence of the bile on the movements of, 439; malformation of, 21; muscular exercise or quiet in disease of, 554; paroxysmal tachycardia, 495; prognosis in diseases of, 648; propagation of murmurs, 269; puncture of, in chloroform narcosis, 644; safety valve, action of, 664; syphiloma of, 297; valvular disease of, without serious symptoms, 437; with a double mitral orifice, 307.
Heart-beat and respiratory changes, 659.
Heart-strain, 229, 250.
Heat, animal, relation of muscular action to, 74.
Heaton's method of curing hernia, 258.
Hedges, Dr. E. W., danger in toast, 136.
Hematocele, pelvic, 140.
Hemiatrophy, progressive facial, 428.
Hemorrhage and aneurism, 548; and antisepsis, 638; nasal, 592, 672; intra-peritoneal in the new-born, 437; middle meningeal, 623; post-partum, 156; uterine, hydrastis in, 712.
Hemorrhoids, internal, 711; painful, 434.
Henderson, Dr. R. B., two cases of poisoning, 95.
Hernia, 159; reducible and irreducible, 258; statistics, 172; strangulated, 389; strangulated, danger of hypodermics of morphia in, 536; treated by subcutaneous injection, 35; ventral, 619.
Herniotomy under cocaine, 124.
Hip, congenital dislocation of, 675; epiphysitis of, 264, 277.
Hip-joint disease, 585, 612.
Hogshead, Dr. D. P., pneumonia in the country, 422.
Holt, Dr. L. E., empyema in children, 602.
Homans, Dr. John, wounds of the bladder, 69.
Homœopath, the position of, 691.
Homœopathy at Ann Arbor, 416; Hahnemanian, 219.
Hooker, Dr. Alfred Edwards, death of, 526.
Horn growing from the human head, 424.
Horse, doctor's, 422, 507.
Hospitals, contributions to London, 99; for all England, 199; maternity, 413; mortality in lying-in, 414.
Howe, Dr. L., rough-and-ready country experience, 338.

Terebene, palatable, 200.
Testimony, compensation for expert, 44.
Tetanus, antipyrin in, 431; infectiousness of, 75.
Therapeutics of mineral waters, 38; Paris hospital, 564.
Thinking and working, 256.
Thirst in young infants, 591.
Thomson, Dr. W. H., word-blindness of aphasia, 291; treatment of the upper air-passages, 490.
Thread-worms in children, 170.
Throat, constitutional causes of affections of, 672; sensory affections of, 648.
Thumb-sucking, 548.
Tipton, Dr. Frank, intubation of the larynx, 608.
Toast, danger in, 136.
Tobacco, poisoning by, 546.
Tongue, fissures of, 189; hypertrophy of, 644.
Tonsil-knife, 140.
Tonsillitis, bicarbonate of sodium in, 127, 340; turpentine stupes for, 536; relations of, to scarlatina and diphtheria, 580.
Torticollis, 720.
Trachea, 330.
Tracheotomy, 303, 578; after intubation, 707.
Transactions of the Academy of Medicine in Ireland, 471.
Tubercle-bacilli, 311; demonstration of isolated, 327; simple apparatus for staining, 164.
Tuberculosis and scrofula, 71, 712; bovine, 60; contagion through chickens, 191; from circumcision, 355; natural history of, 70; of the bladder, 215; of the larynx, 659; of the lymphatic glands, 425.
Tubes, frequency of disease of, 703; prolapsed, 66.
Tulipine, 386.
Tumors, micrococcus of, 245; of the bladder, 227, 326.
Turpentine, Chian in cancer, 28.

U

Ulcers, 567; new remedies in, 170; of the stomach in infantile tuberculosis, 256.
Uræmia, morphine in, 530; post-partum and cerebral embolism, 529.
Urea, 480; excretion of, and abdominal tumors, 172.
Ureters, dilated, 362.
Urethan for the insane, 27.
Urethra, gradual dilatation of, 533; irrigation of, 423; minor traumatisms of, 513, 533; nitrate of silver in deep, 598.
Urethritis without gonococci, 521.
Urethrotomy, external, 513, 533.
Uric acid diathesis, 466.
Urinary infiltration, 713.
Urine, best tests for albumin in, 484, 502; fermentation test of, for sugar, 91; importance of examination of, in infants and young children, 158; lead in, 695; normal, creatinine in, 411; retention of, 595.
Urticaria, 394; from cow's milk, 112.
Uterus, cancer of, 107, 161; cancer developed in the site of an old laceration, 363; carcinoma of the, 437; elastic ligature for fibroids of, 395; fibromata of, Cæsarean section for, 390; fibromata treated with electricity, 637, 640; inversion of, 126; removal of appendages of, 42, 158; retro-deviations of, 520; retroflexions of, 67; rupture of, 335, 449; solid tumors of, 419.
Uvula, 293.

PROGRESSIVE SPASTIC ATAXIA (COMBINED FASCICULAR SCLEROSIS) AND THE COMBINED SCLEROSES OF THE SPINAL CORD.[1]

BY C. L. DANA, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO BELLEVUE HOSPITAL, NEW YORK.

THE object of my paper is to show that there is a class of cases, not very rare, in which the symptoms coincide in a measure with those of locomotor ataxia, but in equal or greater measure with those of another disease, viz., spastic paraplegia; that the pathological anatomy and clinical course of this disease is a tolerably distinct one, and is to be differentiated from other forms of chronic spinal disease; and that, both for prognosis and treatment, it is important to recognize the somewhat special character of the affection.

It has not infrequently been observed that cases, giving a general history of locomotor ataxia of a milder type, present also symptoms of exaggerated muscular irritability and motor weakness; symptoms which, it is admitted, do not belong to posterior sclerosis. No attempt to study these cases systematically and classify them from a clinical standpoint, however, has been made until quite recently.

The symptoms pointed to a combined lesion of the posterior and lateral columns, and in 1885 Dr. Ormerod collected 20 of such cases (*Brain*, April, 1885) and analyzed them. Last year Professor Grasset (*Archives de Neurologie*, 1886, Nos. 32, 33, 34) collected and analyzed 33 cases, in which autopsies had been made, and combined sclerosis of the posterior and lateral columns was found.

Dr. R. Massalongo also made a collection of cases in *Medicina Contemporanea*, October and November, 1886.

The clinical histories in these cases showed very great diversity of symptoms, and it was evident that the collections of cases did not furnish the basis for a single distinctive disorder.

Besides the cases collected by Grasset, I have been able to find accounts of eleven others, and also to present to-night two cases with autopsies not heretofore published. This makes a total of forty-five cases in all.

A study of these pathological findings, and a comparison of them with clinical symptoms, show at once that we cannot establish a new disease with this simple term, combined sclerosis or mixed system-myelitis as a basis.

An analysis of the reports made compels us to make such subdivisions as the following of the cases in which a sclerosis of the posterior and lateral columns of the cord is found.

CLASS I.—A combined sclerosis of the spinal cord may occur in general paresis and chronic mania. There have been reported by Westphal, Zacher, Sioli, and Damaschino, in all seven cases of this kind.

CLASS II.—Out of 101 cases collected by Vicioli, of hereditary ataxia or Friedreich's disease, autopsies have been made in 88 cases. These all (except one) showed combined sclerosis of a somewhat severe and peculiar type, and with evidences of imperfect development of the cord.

CLASS III.—Combined sclerosis has been noted in cases of evident progressive locomotor ataxia, in which flaccid or contractured paralysis had finally developed (paralytic tabes). Ten cases of this kind are recorded.

CLASS IV.—Cases of primary spastic paraplegia or pseudo paraplegia, with ataxia and sensory disturbances (progressive spastic ataxia). Ten cases.

CLASS V.—Cases having symptoms of spastic paraplegia and of locomotor ataxia about equally developed, forming also a type of progressive spastic ataxia. Six cases.

CLASS VI.—Miscellaneous cases presenting very irregular symptoms, and showing post-mortem dorsal myelitis, posterior sclerosis, with disseminated lateral sclerosis, etc. Four cases.

We have, therefore, combinations of posterior and lateral sclerosis:

I. In mania, seven cases.

II. Friedreich's disease, eight cases.

III. Paralytic tabes, ten cases.

IV. Progressive spastic ataxia (motor or spastic symptoms predominant), ten cases.

V. Progressive spastic ataxia (sensory or tabetic symptoms more prominent), six cases.

VI. Unclassified cases, four cases.

Now, for clinical study we cannot utilize very well the cases of combined sclerosis occurring in the insane (Class I.), although one of them, Sioli's, was of such typical character as to be important.

The combined sclerosis, in Friedreich's disease (Class II.), is only part of the lesion, and the disease itself produces no spastic, and only very late paralytic, symptoms.

Tabes dorsalis with flaccid paralysis (Class III.) is not very rare. Indeed, some motor weakness in this disease is very common. In these cases of paralytic tabes dorsalis with combined sclerosis, it is impossible always to say how the paralysis is caused. Such paralysis does not indicate any extensive involvement of the lateral columns, but rather a severe posterior sclerosis, a somewhat marginal antero-lateral sclerosis, or a diffuse extension of the lateral sclerosis in the dorsal region. Sometimes it is partly neuritic.

These cases do not belong to the type of *progressive spastic ataxia* under consideration, and will not be further discussed.

We have, therefore, left but two of those classes of cases (Classes IV. and V.), sixteen in all, showing combined sclerosis and agreeing with the clinical types under present discussion. These are the only cases in which the pathological findings have a direct bearing.[1]

I present here a summary of the history of the cases and of the pathological findings, coming under Class IV. and V. with illustrations showing the extent of the lesion at three levels—middle cervical, middle dorsal, and middle lumbar. The shadings indicate the sclerotic or degenerated parts, and have all been copied from the original illustrations, except in one case.

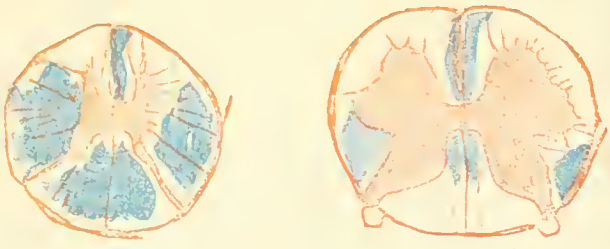
FIRST, cases in which symptoms of locomotor ataxia and spastic paraplegia were pretty equally combined, forming class (*a*) of progressive spastic ataxias.

CASE I.—Damaschino (*Gazette des Hôpitaux*, No. 1, 1883), in a clinical lecture, says he has made autopsies on three cases, and found combined sclerosis. The

[1] Read at a meeting of the New York Academy of Medicine, February 17, 1887.

[1] It is but right here to call attention to the somewhat uncritical way in which Professor Grasset, whose work is generally so admirable, has massed all cases of combined sclerosis together and endeavored to make one disease of them. He has in his tables cases of Friedreich's disease, chronic mania, dorsal myelitis, and amyotrophic lateral sclerosis, and endeavors to raise a clinical specire from the dry bones of this pathological miscellany.

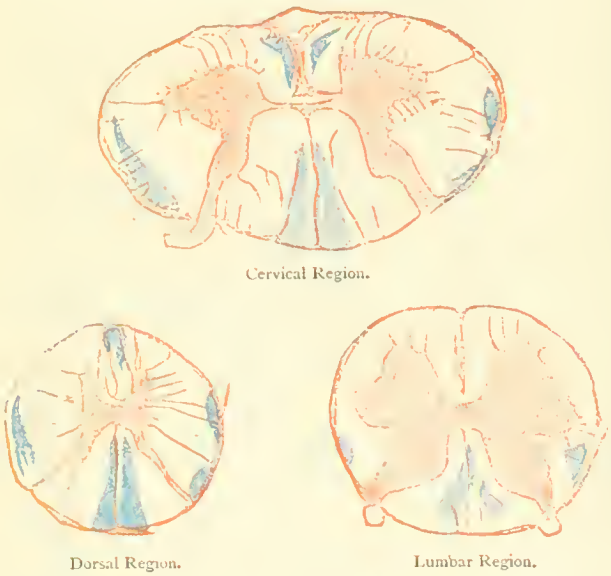
symptoms were first those of ataxia, then more or less weakness of lower limbs; then stiffness, trembling, cramps, loss of tendon reflex; no epileptoid trepidation.



Dorsal Region. Lumbar Region.

In *one case* the lateral columns were affected less in lower part; in cervical part, only the columns of Goll affected. The posterior sclerosis is marginal. *General course:* That of *tabes with paraplegia* and some spastic symptoms.

Case II.—Sioli (*Archiv f. Psych.*, vol. xi., 1881): Male, aged thirty-nine. Severe fall and spinal concussion. Progressive paraparesis, pains, hyperæsthesia, spastic symptoms at first; finally, loss of knee-jerk, atrophy of legs, chronic dementia.



Cervical Region.

Dorsal Region. Lumbar Region.

General course, of a chronic, painful, wasting paralysis, with at first spastic symptoms.

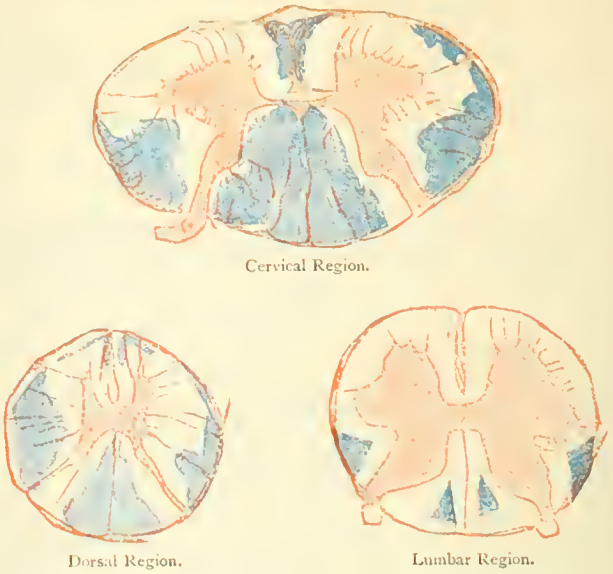
Autopsy: Intense degeneration of direct cerebellar tracts in whole course. Degeneration of direct and crossed pyramidal tracts from lumbar to lower sacral. Diffuse sclerosis to some degree in upper dorsal region, lateral columns. Degeneration of columns of Goll from nuclei to lower limit of cervical region; below this the degeneration extended over to the columns of Burdach, and was slight in intensity. Atrophy of cells of columns of Clark and of anterior cornual cells, especially in the dorsal region.

Case III.—Westphal (Case VII., *Arch. f. Psych.*, vol. xvii, Hft. 2): Male, fifty; heredity good, no syphilis. In 1882 began to have pains, paræsthesia, ataxia, giddy sensations; later, feebleness of limbs. Ataxic symptoms and paresis progressed; retention of knee-jerk, but no ankle clonus or paradoxical contraction; eye symptoms, muscle tension, progressive feebleness, finally loss of knee-jerk.

Duration, two years.

General course, of locomotor ataxia with paraparesis, muscular tension, and retention of knee-jerk till late.

Autopsy: No meningitis; considerable atrophy of posterior roots in lower half of cord, and of anterior roots in dorsal region. Degeneration of posterior columns most marked in upper dorsal region, and absent in lower lumbar region. Degeneration of motor tracts and cerebellar tracts most marked in upper cervical region; cells of Clark's columns atrophied.



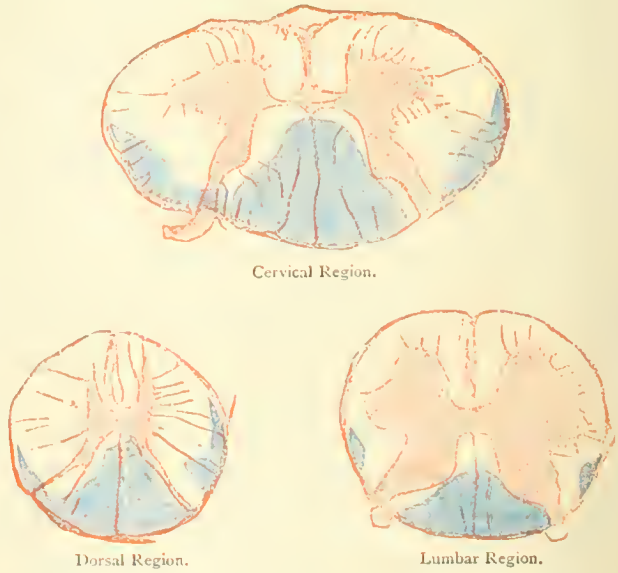
Cervical Region.

Dorsal Region. Lumbar Region.

Case IV.—Prevost (*Archives de Phys.*, p. 764, 1877): Male, aged fifty-one. No heredity. Exposure. Feebleness in lower limbs and right arm, and painful defecation. Within a year bed-ridden. No lightning pains; but paræsthesia; ataxia in upper and lower extremities; paraplegia, hyperæsthesia, but no anæsthesia except slight just before death. Great exaggeration of reflexes. Blindness, myosis. No muscular atrophy except of hands and arms.

Duration, ten years.

General course of tabes with spastic symptoms and ataxia, and paraplegia, without anæsthesia or pains.



Cervical Region.

Dorsal Region. Lumbar Region.

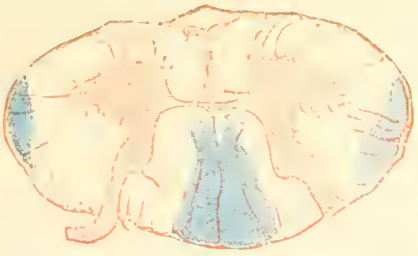
Autopsy: Atrophy of posterior roots in dorsal region. No meningitis. Sclerosis most marked in dorsal region.

Case V.—Dejerine (*Arch. de Phys.*, iv., 1884): Female, aged fifty-two. Fulgurating pains for years; paresis in legs for two years, with stiffness; anæsthesia in plaques; ataxia; no muscular atrophy; exaggerated reflexes; no bladder troubles; arms not affected. Death from pneumonia.

General course, that of *tabes with slight paresis and spastic symptoms* supervening.

Autopsy: Sclerosis of lateral pyramids in lumbar and lower dorsal regions. Sclerosis of postero-median

column, whole length of Burdach's column in lumbar region. Chronic leptomeningitis. Parenchymatous neuritis of posterior roots and cutaneous nerves. The posterior sclerosis was the older.



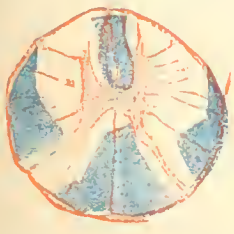
Cervical Region.

Dorsal Region.

Lumbar Region.

Case VI.—Babinski and Charrin (*Revue de Médecine*, November, 1886): Male, aged forty-three; no heredity, except phthisis; no syphilis, or alcoholism; began sixteen months before death; paresis of lower limbs; later fulgurating pains, gastric and rectal crises; marked ataxia; no anæsthesia, except that temperature sense is blunted; exaggerated reflexes; contractions; spinal trepidation; later, myosis; increase of spastic symptoms; anæsthesia increased; analgesia; complete paresis of bladder.

Cervical Region.



Dorsal Region.

Lumbar Region.

General course of ataxia and spastic paraplegia combined, the ataxia preceding.

Autopsy: Primary sclerosis of posterior columns, of lateral pyramids, cerebellar tracts, and columns of Türck; pia thickened posteriorly; posterior sclerosis the older.

Second, cases showing the symptoms of spastic paraplegia plus some sensory disorders, from the type (*b*) of progressive spastic ataxia.

Case I.—Mr. J. Hopkins, reported in *Brain*, October, 1883: Male, aged twenty-one, no syphilis, had fits when young; heredity good.

Symptoms of spastic paraplegia, with no sensory symptoms except tactile anæsthesia of soles of feet. Decubitus.

Duration, two years. Latterly some atrophy of legs.

General course, one of primary spastic paraplegia with some anæsthesia

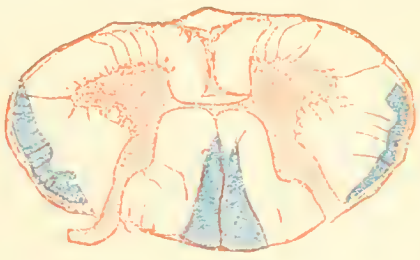
Cervical Region.

Dorsal Region.

Lumbar Region.

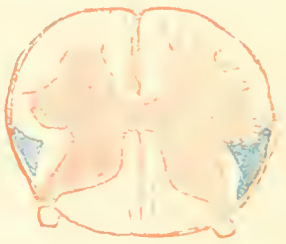
Autopsy: Showed lateral sclerosis of whole length of cord, beginning with lower cervical region; in dorsal region affecting large part of lateral columns, lower down affecting only pyramidal tracts. Posterior sclerosis in whole length of dorsal cord. Very slight in mid-lumbar cord, as shown.

Case II.—Westphal (*Archiv f. Psych.*, vol. viii., 4, p. 506, l. c., 1877, Case IV.): Male, aged forty-five, neuropathic personal history; chancre in 1851. In 1866, stiffness in gait. Paræsthesia in legs, 1867. No pains, giddy sensations, or eye symptoms. Gradual development of typical spastic paraplegia; exaggerated reflexes, trepidations, etc.; slight disturbances in sensation of lower extremities. No ataxia; no eye symptoms; slight bladder troubles; motor weakness. Death from phthisis.



Cervical Region.

Dorsal Region.



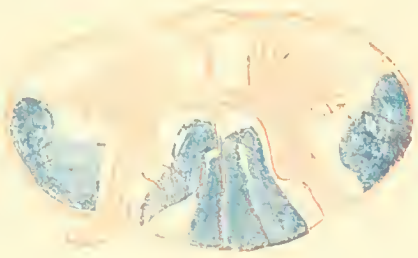
Lumbar Region.

Duration of course, eight years.

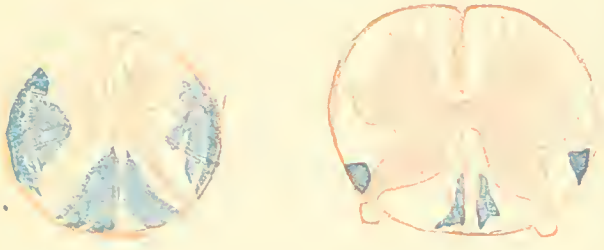
General course, one of chronic spastic paraplegia, with development later of slight sensory symptoms in lower limbs.

Autopsy: Meninges thickened; anterior and posterior roots normal; sclerosis of pyramidal and cerebellar tracts, whole extent; sclerosis of posterior columns above lower dorsal region, mainly of columns of Goll. Disease most marked in upper dorsal region.

Case III.—Strümpell (Case II., *Archiv f. Psych.*, xi., 1855): Female, aged sixty-two. Contractures; atrophy; paralysis; exaggerated reflexes; no pains; anæsthesia in lower extremities; bladder trouble. Death in six months, phthisis.



Cervical Region.

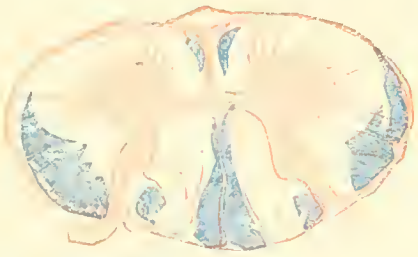


Dorsal Region. Lumbar Region.

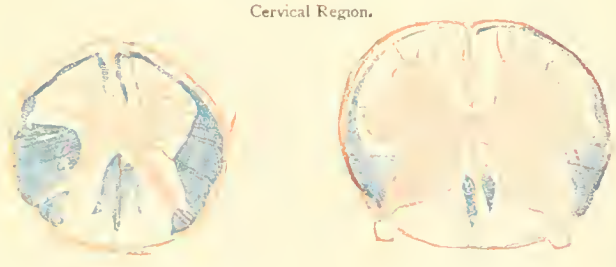
Symptoms of amyotrophic lateral sclerosis, with impaired sensibility. History very imperfect.

Autopsy: Lesions of columns of Goll in whole length and of the root-zones in upper part of cord; also of pyramidal tracts and direct cerebellar tracts, the latter being more marked. The three long fibre-systems were thus affected, the degeneration ascending in the pyramidal tracts, descending in the columns of Goll.

Case IV.—Strümpell (*Arch. f. Psych.*, vol. xvii., No. 1, Case III.): Male, aged fifty-six; neuropathic family. Patient was much exposed to wet; began to have stiffness in legs in 1856; symptoms of spastic pseudo-paraplegia continued thirty-three years; finally some paresis; no sensory, bladder, eye, or sexual troubles. Death from phthisis.



Cervical Region.



Dorsal Region. Lumbar Region.

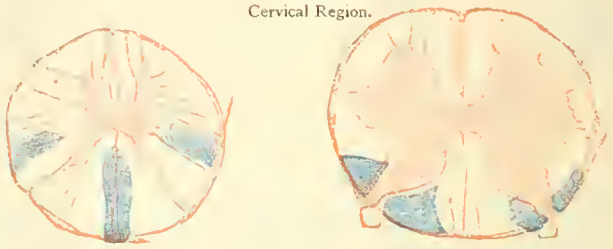
Duration, thirty-one years.

General course, of pure *primary spastic pseudo-paraparesis.*

Autopsy: No meningitis. Nerve roots normal. Degeneration of pyramidal tracts through whole cord; of cerebellar tracts and columns of Goll; columns most marked in upper part of cord. (Strümpell thinks this represents a special distinct type of combined sclerosis.) There was marginal sclerosis, but no meningitis.

Case V.—Raymond (*Archives de Physiologie*, 1882, 10, p. 456): Male; no heredity; no syphilis; aged seventy-eight. Pains in legs for thirty-eight years. In 1875, difficulty in walking; progressive and severer pains. In 1877 could only walk with crutches. Some pain, contractures, cramps. Spasmodic symptoms to less extent in upper extremity. Finally rigid paraplegia, exaggerated reflexes, some atrophy. *No anæsthesia* of any form, no bladder, or eye symptoms; some muscular atrophy; electrical reactions normal.

Cervical Region.



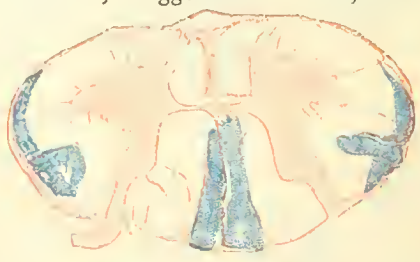
Dorsal Region. Lumbar Region.

Duration, seven years.

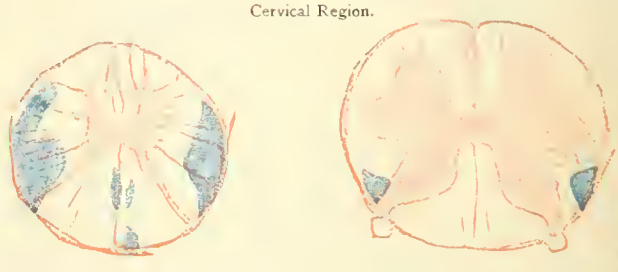
General course: Amyotrophic lateral sclerosis or *chronic spastic paralysis*, with long-continued, painful, and no other sensory symptoms.

Autopsy: Sclerosis of pyramidal tracts most marked in cervical cord; sclerosis of upper part of cerebellar tract; of Goll's columns in cervical and dorsal cord; of Burdach's columns in lower cord. Some atrophy of cells of anterior horns and of Clark's columns. No meningitis. Nerves normal.

Case VI.—Westphal (*Archiv f. Psych.*, Case VI., vol. xv.): Male, aged thirty-eight; no heredity. History of syphilis; development of spastic paraplegia; muscular tension; exaggerated reflexes; foot phenomenon later; partial loss of temperature and muscular sense; ataxia; bladder trouble; increased paresis; involvement of right arm; encephalitis.



Cervical Region.



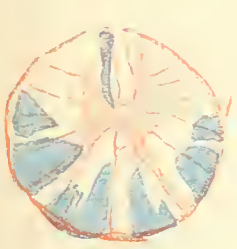
Dorsal Region. Lumbar Region.

General course, of spastic spinal paralysis with slight sensory, ataxic, and bladder symptoms. Five years' course.

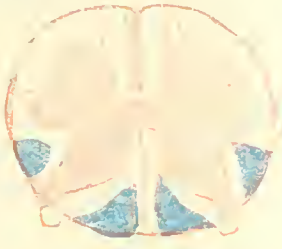
Autopsy: Sclerosis: (1) of lateral pyramids, beginning in middle cervical region, and most marked in dorsal region; (2) of cerebellar tracts, especially in upper part of cord; (3) of Goll's columns, in upper dorsal and lower cervical region, beginning to develop.

Case VII.—Strümpell (Case I., *Arch. f. Psych.*, xi., 32): Female, aged thirty-two. Family history good.

Cervical Region.



Dorsal Region.



Lumbar Region.

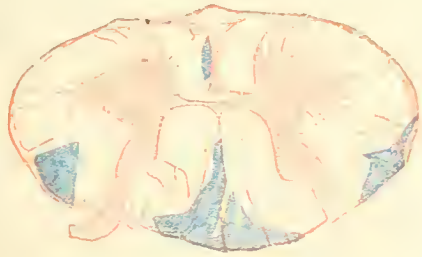
Symptoms. Confined at first and mainly to lower limbs; progressive paresis; atrophy; associated movements; contractures; exaggerated reflexes; paræsthesia; eye and bladder symptoms. No anæsthesia or ataxia.

Symptoms mainly of amyotrophic lateral sclerosis, with painful contractures.

Duration, three years.

Autopsy: Lesion of crossed and direct pyramidal tracts, of direct cerebellar tracts, and of columns of Goll, nearly whole length, and to a slighter extent of inner part of columns of Burdach, above the upper lumbar region; on lower lumbar region, posterior columns not affected; cells of anterior horn not atrophied. Clark's columns atrophied.

Case VIII.—Babesiu (*Virchow's Archiv*, 76, p. 76): Male, aged forty-four, no heredity or syphilis; symptoms began in 1874, no cause; feebleness and stiffness in legs; darting pains in legs and sexual organs; severe contractures; at first exaggerated reflexes; continued paraplegia; paralysis of bladder; total blindness; moderate degree of anæsthesia; no ataxia; bed-sore.



Cervical Region.

Dorsal Region

Lumbar Region.

Duration, three years.

General course, that of *spastic paraplegia with considerable sensory trouble*; also bladder and eye symptoms.

Autopsy: Pia thickened anteriorly and posteriorly. Cells in anterior horns and Clark's columns normal. Sclerosis of lateral columns most marked in dorsal region. Sclerosis of columns of Goll throughout their extent. Brain, normal. Sclerosis most intense in lateral columns, reaching in dorsal region to anterior roots or farther. Sclerosis most marked in lateral columns.

Cases IX. and X. will be referred to later in the reports of my own cases.

Now it will be found, in studying the lesions in these cases, that in most instances the columns of Goll, the lateral pyramidal tracts, and the direct cerebellar tracts, are most affected, often, but not always, throughout their whole course. This tri-fascicular lesion is most typically represented in Cases IV., VI., and VII. of Westphal, Raymond's case, Cases I., II., and III. of Strümpell, and in the cases of Sioli, Dejerine, Babinski and Charin, and Damaschino.

It will also be seen that in the cases primarily of a more spastic type, this purely tri-fascicular lesion is best illustrated. In the more mixed forms it appears that the sclerosis encroaches on the columns of Burdach in the lower part of the cord (Prevost's, Dejerine's, Babinski's, and Damaschino's cases).

When the lesion of the posterior columns encroaches on Burdach's columns in the more spastic cases, it does so in the upper levels of the cord, as in Strümpell's and Hopkins' cases.

The lesion of the lateral columns sometimes extends forward, involving the ascending lateral tract of Gowers, and inward, involving the lateral mixed column (see Westphal's case VII., and the cases of Hopkins and Babesiu). But in these instances the encroachment does not extend far longitudinally.

The columns of Türck are involved in half the cases, either on one or, oftener, on both sides.

The sclerosis in the columns of Goll is generally most marked in the upper dorsal and lower cervical parts of the cord. The same is true of the lateral sclerosis.

The long fibre-systems are always affected throughout nearly their whole length, and this is due to the fact that the sclerosis is *primary*. In primary fascicular sclerosis the degeneration is, or at least may be, in the opposite direction to the course of the impulse it carries, and hence, in the case of the columns of Goll and the direct cerebellar and antero-lateral ascending tracts, it would be downward, diminishing in extent in the lower part of the cord. In the direct and crossed pyramidal tracts the process goes upward, and should be less in the cervical region.

The anterior cornual cells are affected at some levels in cases of the more purely spastic type, or in those in which the dorsal lesion is extensive.

The posterior cornual cells and the cells of the columns of Clark are also affected in the severer sensory types. But as a rule the gray matter is not involved.

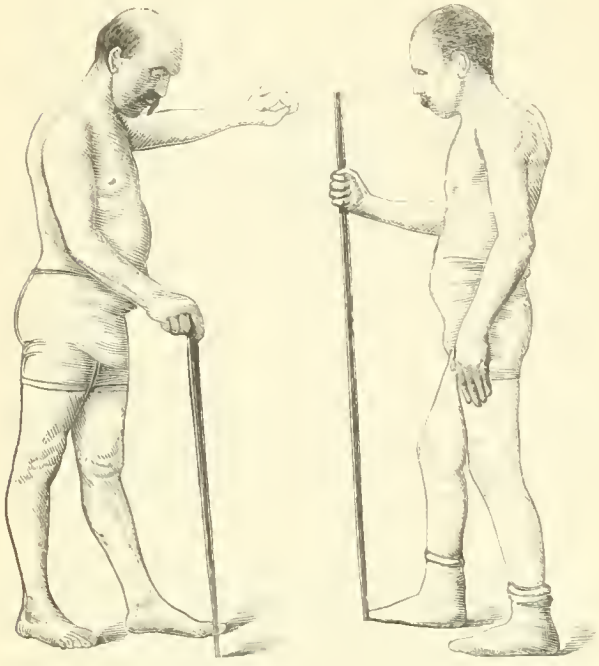
There is often thickening of the meninges, and rarely a chronic lepto-meningitis. Dejerine thinks that by means of the inflamed meninges the process is conveyed from one fibre-system to another, but this view is not shared by any others. Friedreich, who first held to such opinion as explaining the lesions in hereditary ataxia, subsequently abandoned it.

The typical tri-fascicular lesion is a superficial one, and does not involve so much the organic centres of the cord; hence it may spare life for a long time.

Some cases of progressive spastic ataxia are plainly due to peculiar systemic and diffuse lesions combined, not to the typical tri-fascicular sclerosis.

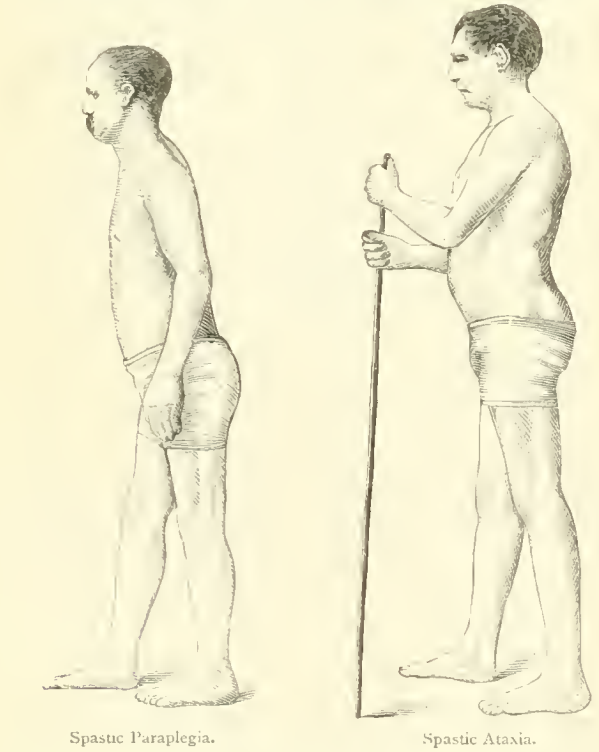
My own case was one starting, probably, as a chronic dorsal myelitis, involving the antero-lateral columns. From this there was descending degeneration, which in the lower part of the cord seemed gradually to extend

over and involve the postero-external column. Then the columns of Goll became affected above, as shown in the cuts. There was undoubtedly an acute process supervening shortly before death. In Dr. Hammond's case there was a lesion at the lower end of the col-



Typical Locomotor Ataxia. Transverse Myelitis.

umns of Goll with ascending degeneration of a peculiar type (vesicular degeneration of Leyden), occupying the whole length of the strand. The degeneration in the lateral and cerebellar columns was much less marked, and was apparently greater in the upper part. The patient's history was one of very marked spastic and ataxic



Spastic Paraplegia. Spastic Ataxia.

symptoms. He had phthisis, which prevented his living to the development of a tri-fascicular sclerosis in a typical manner.

It thus appears that we cannot yet speak with certainty of the lesion of progressive spastic ataxia, or ataxic hemiplegia; but it *seems probable that the typical classical lesion is one involving the three long fibre-systems, primary in character, and most marked in the dorsal portion of the cord.*

If this were the case the pathological name for the disease would be "combined fascicular sclerosis." Strümpell seems inclined to take this view.

Clinical History.—Turning to the clinical side of the matter we find that Gowers, during the past year, has described a type of disease which he calls ataxic paraplegia, and which is intended to cover the class of cases under discussion. "Ataxic paraplegia" is spastic paraplegia plus ataxia.

The term "ataxic paraplegia" is objectionable, in my opinion, because many cases lack until very late the paraplegic element, and even the ataxia may be absent also, as in Case I. of my own. The most constant and characteristic symptoms in my own cases, however, were the ataxic and the spasmodic. I, therefore, selected the term progressive spastic ataxia, admitting at the same time its imperfections.

Spastic Ataxia. Spastic Ataxia.

As to the general clinical features of these cases, I have found that the larger proportion present a background of tabes dorsalis in its milder, less painful form, plus spasmodic symptoms. In a smaller number of cases spasm and ataxia are altogether the dominant symptoms, and true tabes dorsalis is hardly suggested.

I shall not attempt to give any extended description of this disease, for it has been admirably done, from one point of view, already by Dr. Gowers. What I may say is based upon thirteen cases of my own and the sixteen cases with autopsies collected elsewhere.

Etiology.—In my own cases the proportion of females to males was as one to six. The age ranged from nineteen to fifty-two, several of the most typical cases beginning in persons between twenty and thirty. A neuropathic history was present in three cases, syphilis in two, hard physical work and exposure in three, various excesses—sexual, alcoholic, and physical—in one.

There was spinal myosis in two, but in only one was there optic atrophy or serious eye trouble.

In the males the sexual power was uniformly lost quite early; then some bladder trouble, slight in degree, followed.

Taking all the cases (twenty-seven) together, I find that syphilis was rare, not being present in more than

five per cent. It is, however, unquestionably sometimes a factor. Heredity is also an important factor. Spastic ataxia even shows a family type, as in the cases of Striimpell.

In cases occurring in early life, sexual and alcoholic excesses are noted, while if the disease comes on later it is due to hard physical strain and exposure. Two of my patients were stone masons.

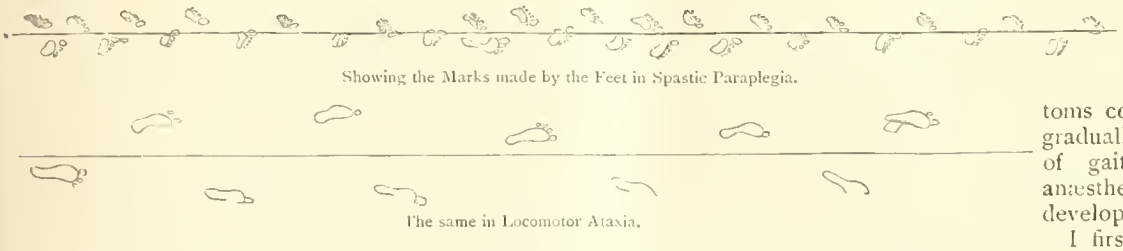
I think that hysteria may produce a functional disorder very like spastic ataxia, but recognizable by the mutability of symptoms, irregular course, and past history.

Onset and course.—Taking my own cases alone, I found that the *first symptoms* were stiffness in the legs, followed quickly by pains, in one case; ataxia in four cases; paresis and cramps in one; paræsthesia, pains, and ataxia in one. Only one suffered greatly from pain at any time.

The general type was mainly ataxia with spasm in four; a very equal distribution of tabetic and spasmodic symptoms in two other cases.

Considering all the cases together, the onset may be described as follows:

It begins usually with ataxia, then stiffness and trembling in the legs are noticed, sexual power early declines, then there is temporary bladder trouble, generally a retention or slowness in emptying the bladder. Feelings of numbness and heaviness are early observed; there are pains of a fulgurating character, but they do not last long; sacral and lumbar pains are frequent, as Gowers observes, and sometimes these are all the pains complained of. Girdle pains are absent, as a rule.



Showing the Marks made by the Feet in Spastic Paraplegia.

The same in Locomotor Ataxia.

As a rule the disease is a painless one. Patches of anæsthesia are noticed. These often go away under electrical or other treatment. There is rarely much tactile, pathic, or temperature anæsthesia, and muscle sense is often good. The eyes are rarely involved, and there are no gastric or enteric crises.

Marked motor weakness, noticed by Gowers, is not present, as a rule. It was absent in one-half of Westphal's cases, and in a larger proportion of mine.

Muscular tension, exaggeration of the deep reflexes, paradoxical contraction are present, and are striking features. The plantar reflex is often extremely lively.

The symptoms begin in, and are usually confined to, the lower extremities, but sometimes the arms are also involved.

The ataxy is almost always present, and is decided. It is shown in standing and walking, and in attempting to make co-ordinate movements. It is present even when the muscular sense, as tested by posturing the limbs and by weights, is shown to be good.

The gait is a combination of that in tabes and in spastic paraplegia. The heels are brought down first in some cases, in others the toe drags and is brought down first. In some cases the whole foot is planted down at once, and the shoes are worn almost evenly.

The attitude as shown by the accompanying photographs, when compared with that of typical tabes or typical spastic paraplegia, represents a union between the two.

Illustrations of the gait, as shown by the marks of the feet, are also given. These are taken from Gilles de la Tourette's "Clinical Studies of the Gait in Paralytics."

I present here a history of my own cases.

Case I. *Male, aged thirty; psychopathic family history; early venereal excesses; syphilis; anæsthesia and pains; rigidity of extremity; exaggerated reflexes; tremors; Argyll-Robertson pupil; vesical paresis; impotence; progressive increase of spastic symptoms; no atrophy or paralysis; duration, nine years.*—J. L. G——, male; aged thirty; single; United States.

Family history.—The parents were healthy. An aunt was insane, an uncle committed suicide, another was insane.

Personal history.—The patient was a healthy boy, but sexually precocious, and early began to commit sexual excesses. At the age of twenty he became engaged, and at this time suffered greatly from sexual emissions, and became somewhat hypochondriacal. He had two epileptoid attacks at about this time. In 1876 he contracted syphilis, and at about this time indulged excessively in sexual intercourse. He had a stricture develop as the result of an old gonorrhœa. In 1878 he first began to feel spinal symptoms. He states that he became intoxicated one evening, and next day his legs felt very stiff, so that he could hardly lift one over the other; but he had no pains. This stiffness passed away in about six weeks. He then felt some sharp, lightning-like pains at times in the legs. His sexual power rapidly declined, and finally erections became impossible, though desire still remained. He noticed that his right pupil was larger than the left. His bowels were constipated. These symptoms continued, and gradually a stiffness of gait and some anæsthesia of the legs developed.

I first saw him in the fall of 1884, eight years after his first symptoms had been noticed.

Examination.—His general appearance was that of a fairly nourished man, not anæmic. His gait was slightly spastic and jerky, not ataxic. His organs were healthy aside from the nervous system. The mind was clear and sleep good. There was no paralysis of any part. Dynamometer, right hand, 45; left, 40. The triceps-tendon and wrist-tendon reflexes were exaggerated, especially on the left side, but there was no ataxia of the arms. Occasionally he had a slight tremor in the left hand. No atrophy. The lower extremities were not paretic, but there was tension of the muscles; the plantar reflexes were greatly exaggerated, and a sudden blow on the spinous processes from the mid-dorsal region down produced contraction of the adductors of the thigh. Electrical sensibility and irritability normal. The patient could control his limbs well and had no ataxia, but had painful cramps and trepidation in them at times.

Sensory: The patient suffered from lightning-like pains in the legs and soles of the feet, and had subjective sensations of coldness in the feet. Temperature of left foot, inner side, 96.5° F., *i.e.*, normal. Tactile and pathic anæsthesia noted in slight degree in feet and legs. He had decidedly anæsthetic patches in different places. He had had hyperæsthetic spots also. Conduction of sensation not delayed. The temperature sense was affected. He had no ataxia, and could walk in the dark. The plantar reflexes are exaggerated, cremasteric reflex absent, other skin reflexes normal. He had vesical weakness and sexual impotence. The heart was irritable. The eyes showed mydriasis of right pupil, and loss of light reflex nearly complete in both pupils, also myopia. There was some difficulty in swallowing, owing to morsels of food catching in the laryngeal pouches.

During the next twelve months the patient's symptoms slightly improved. The anæsthesia of the feet and legs

and the darting pains were less. The painful cramps continued. He slept well when lying flat on the back.

Two years after the first examination he developed a rectal ulcer, which made it almost impossible to retain the fæces. This was relieved temporarily by applications of nitrate of silver and nitric acid. The patient's anæsthesia, which had partly disappeared, had returned, and the spastic symptoms slightly increased. There was a tremor and some atrophy in the left arm. He still has no ataxia, and can write well and walk in the dark.

As to treatment, under large doses of the iodides, and occasionally a course of mercury, his symptoms improved. Iodide of ammonium agreed with his stomach best. He took digitalis at times for the relief of his irritable heart.

It will be seen that we have here the eye, bladder, cardiac, pneumogastric, and sensory symptoms of locomotor ataxia, but predominating over these the symptoms of spastic spinal paralysis.

Case II. *Female, aged twenty six; neuropathic family; personal history good; symptoms began July*, 1885; *numbness and slight weakness of lower limbs; ataxia in all limbs without anæsthesia; spastic symptoms; exaggeration of reflexes; clonus; no atrophy; no paralysis; slight anæsthesia; vesical weakness; no eye symptoms.*—Jane D——, aged twenty-six; single; New York; seamstress.

Family history.—The patient's grandmother was epileptic. The father is of nervous temperament, and has nervous dyspepsia; he used to drink excessively, though not an inebriate; also used a great deal of tobacco. Three sisters died of convulsions when infants. Three sisters, still living, are very nervous.

Personal history.—The patient has been of a nervous, excitable disposition. When a child, used to have attacks of complete mental confusion, perhaps of an epileptoid character. Has worked at a sewing-machine a good deal. Menstruated at about fourteen, and has had no pains or trouble at this period, but her courses are scanty. She has lived a quiet, temperate life, and has shown no evidences of hysteria.

In the summer of 1885 she first began to notice her present symptoms. She caught cold at this time, and then noticed a numbness in the legs and a weakness and uncertainty in walking. There was numbness to a less extent in the arms. She had icy-cold sensations about the waist, some difficulty in passing urine, and constipation, but no pains anywhere. She had some dyspepsia, acid in character. These symptoms of numbness and weakness continued, to which were added stiffness of the legs and occasional cramps.

Examination.—She was seen by me in October, 1886, fifteen months after the symptoms first began. Her appearance is that of a well-nourished person, neither emaciated nor fat. Her gait is uncertain, stiff, and jerky; the feet come down strongly, the left toe barely leaving the ground, the heel striking the ground last; the body sways, and the line of movement is irregular. The gait is not typically spastic, but it is rather that of muscular stiffness and ataxia combined.

On examination I found no abnormalities of the skull, the mind was clear, not irritable, but somewhat depressed. Her sleep was good; she had no vertigo or headache, nor any hysterical crises; no disorders outside of the nervous sphere. Her urine contained a trace of albumen, was cloudy, yellow; specific gravity 1.020; no sugar; phosphates and urates normal or below the average.

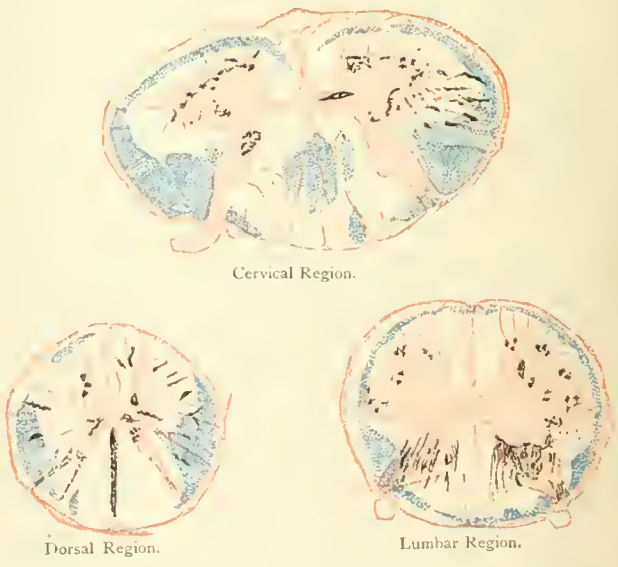
Her arms showed slight muscular weakness; dynamometer, right hand, 35; left, 29. Her lower limbs are perhaps a little weak, but the gross strength is still good, and she can walk a considerable distance. There was no atrophy or change in electrical reactions; there was no tremor, but the deep reflexes were exaggerated. There was ankle clonus; no paradoxical contraction; the plantar reflexes not much changed. She had contractions, trepidation, and cramps in the legs. She had both static and locomotor ataxia of moderate grade, due to impaired muscular sense. This ataxia affects the lower limbs mainly. She can sew, but sometimes drops her needle, because she can't feel it, and she is a little awkward with her hands. With closed eyes she shows a little uncertainty in touching the tip of her nose with her forefinger. There is a slight degree of tactile anæsthesia in the lower limbs. She has no neuralgic or lightning pains. At one time there was vesical weakness, but this has now disappeared. She suffers from constipation and dyspepsia, with acid eructations and boulimia. Her courses are regular, painless, scanty, and not accompanied with any exaggeration of symptoms. She has had no pains at any time. The pupillary reflexes are normal; there are no ocular paralyses. She has astigmatism and myopia. Fundus normal.

During the four months in which she was under observation her symptoms continued about the same.

Case III. *Female, aged nineteen; family history good; patient of nervous temperament; supposed hysterical attacks between ages of eight and ten; severe mental and emotional strain at sixteen; ataxia and anæsthesia, with spastic symptoms affecting different extremities for three years, but mainly lower limbs; temporary visual trouble; diplopia and vesical paresis; no neuralgic pains; when seen by writer at end of three years, spastic ataxia with cutaneous anæsthesia, mainly in left arm and right leg; some improvement with shifting of symptoms; mental depression; no hysterical crises.*—Patient referred to me by Dr. William O. Moore. K. P——, aged nineteen; single; United States.

This patient's history is much like that of Case II, being apparently a hysterical case. The details are therefore omitted.

Case IV. *Female, forty-two years of age; widow; negative family history; possibly syphilis; alcoholic and other excesses; in* 1883 *paraparesis; paræsthesia; slight pains; spastic symptoms; anæsthesia of lower limbs; bladder troubles; death*, 1886; *duration, three years; autopsy.*—This patient was brought to Bellevue Hospital in the service of Dr. E. Darwin Hudson, Jr., to whose kind-



Cervical Region. Dorsal Region. Lumbar Region.

ness I am indebted for the opportunity to examine the cord and use the notes. I am also under great obligations to Dr. John H. McGivern, of this city, for kindly supplying important details in the history.

Mary N——, forty-two years of age; widow; United States; housekeeper; admitted to Bellevue Hospital October 23, 1886. The family history is good, so far as nervous disorders are concerned. About ten years before admission patient led a fast life, indulging in alcohol. She showed some syphilitic symptoms, but never acknowledged having had that disease. About

three years before admission to the hospital she began to suffer from paralytic symptoms. These were confined always to the lower extremities. They began with numbness and tingling. She had stiffness of the joints and pains in the lower extremities and in the lumbar region. She suffered especially from spasmodic contractions, trepidation, and cramps in the limbs. The pains were worse in the last year or two. The symptoms gradually increased until she finally had to go about on crutches. The decided paraparesis began six weeks before admission.

There developed gradually a weakness and finally paresis of the bladder, so that on two occasions, about three months previous to death the urine had to be drawn by a catheter. The urine was then high colored and albuminous. From this date she had dribbling of urine. Anæsthesia of the lower limbs was noted by Dr. McGivern at this time. The legs and abdomen became œdematous at this time, and she suffered from headaches, vertigo, dimness of vision. The bowels were constipated.

On admission the patient showed no signs of emaciation. There was an eczematous condition of the chest and back. Heart and lungs were normal. Urine acid, 1.018; no sugar; trace of albumen; no casts. There is loss of power in the lower extremities, and patient can only walk with help. The legs are not atrophied. There is some anæsthesia and ataxia, as shown by inability to place the limbs at a given spot. The knee-jerk is diminished.

A week after admission the patient developed a sacral bed-sore. She began to pass her urine and fæces involuntarily, developed an adynamic condition, the bed-sore spreading, and she died on November 13th, three weeks after admission.

Autopsy, made the same day.—Heart, lungs, liver, and spleen normal or nearly so; kidneys are enlarged to about one-half; capsules thickened and somewhat adherent; cortex congested and slightly thickened; striæ invisible; pyramids congested; mucous membrane of pelvis congested. Brain: Pia mater congested and thickened over the convexity; no serum in ventricles. Spinal cord: Meninges much congested. On section of the cord a wedge-shaped tract of grayish color is found in the posterior part of the lateral columns. It is bilateral and is most marked in the cervical enlargement, but shows plainly throughout the dorsal region.

Microscopically: Sclerosis of *crossed pyramidal* tracts most marked in dorsal region. Sclerosis of *cerebellar* tracts to a moderate extent. Sclerosis in *columns of* Goll most marked in cervical region, less in dorsal. In the cervical region the sclerosis is diffused, affecting nearly the whole lateral column. There is very great increase in number of vessels in anterior cornua and lateral columns, and to a less extent in posterior and anterior columns, all being most marked in lower cervical and upper dorsal regions. Evidence of an acute process beginning in posterior horns at a low level of cervical cord. Cells of anterior horns affected in cervical and dorsal region at some levels—affections recent. Cells of columns of Clark atrophied at upper levels.

Anatomical Diagnosis: Chronic cervico-dorsal myelitis affecting lateral columns primarily; gray matter secondarily; secondary degenerations in lateral column; ascending and descending development of sclerosis in columns of Goll.

Case V. *Patrick C——. Family history negative; possible syphilis; hard drinking and heavy work; ataxic symptoms; impotence; some darting pains; no anæsthesia; spastic symptoms; temporary bladder trouble; vision slightly impaired; course seven years.*—Patrick C——, aged fifty-one; Ireland; laborer at stonework. Family history negative. Patient has been a heavy drinker; has worked very hard, doing heavy lifting, etc. Had a venereal sore twenty years ago. His health has been very good until the year 1880, when he noticed that in using the hammer and drill he often struck his hands. His gait was also uncertain; his sexual power declined. In 1881 he had some pains in the lumbar region, and darting pains in the knees and outer aspect of the legs. He noticed that when walking after dark, he would reel like a drunken man. In 1883 his eyesight became poor. His sexual power was abolished. He had trembling of the legs, painful contractions, and involuntary trepidation of the lower extremities, especially when in bed, so that the whole bed was shaken. Occasionally he had attacks of painful diarrhœa, and his bladder became weak, so that he could not readily pass his water.

Patient was admitted to the hospital in October, 1886.

Physical examination.—Patient is a large man and not emaciated. His gait is ataxic, but there is jerkiness and wide-spreading of the feet in addition. No troubles were noted outside the nervous system.

His mental condition is good, he has no vertigo, and he sleeps well except for the cramps and spinal trepidation. His muscles show no atrophy, nor is there any very noticeable loss of power in any of the extremities. Dynamometer, right hand, 50; left, 55. (The average pressure in my dynamometer is between 40 and 50 for men.) Electrical reactions normal.

The muscles show exaggerated response to mechanical irritants, *i.e.*, blows over the motor point or body of the muscle. Patient complains of some heaviness in the legs, but has no paræsthesia or pains, or sense of anything between the soles of the feet and the ground when he stands.

The special cutaneous senses are all normal; he even appreciates slight differences in weight and pressure. He shows, however, a very marked degree of ataxia in all the extremities, but especially in the lower, as tested by making him pose his limbs and touch certain parts of the body. He cannot stand or walk with the eyes closed.

There is very great exaggeration of all the deep and cutaneous reflexes. Paradoxical contraction is present, lasting about twenty seconds. The patient has a double patella reflex, the first being probably myotatic, the second a skin reflex. The pupils are small and very sluggish to light; accommodation reflex present. Fundus, normal.

The other special senses are normal. The bowels are constipated; the bladder is at present normal.

Under treatment, the patient improved greatly as to both sensory and motor symptoms.

Four months later he had no spinal trepidation, the plantar reflexes became almost normal, and the ataxic symptoms decreased.

Case VI. *Male, aged twenty-eight, single; good family history; personal history of vinous, venereal, tobacco, and saltatory excesses; syphilis doubtful; gradual onset during four years of ataxia, slight pains, and anæsthesia; severe spastic symptoms; exaggerated reflexes; spinal trepidation; vesical and sexual weakness; symptoms confined to lower extremities; eyes not affected.*—The patient was sent to me by my friend, Dr. De L. Carter.

C——, male, aged twenty-eight; single; United States, book-keeper. The parents were healthy; one brother has a spinal trouble (curvation?). The patient had always been strong and healthy. He has smoked and drank a great deal, and indulged in sexual excess. He has danced a great deal. He had gonorrhœa and a soft chancre, but gives no history of syphilis.

In 1881, five years before I saw him, he began to notice some weakness and uncertainty in his legs, but this did not interfere with his regular work, or his pleasures, until a year ago (1885), when his ataxia became too great to allow him to dance. He noticed that his legs were weak and stiff, and sometimes there was trepidation in the legs. His hands and arms were not affected at all. He had some sharp, twitching pains in the legs occasionally, but these were slight in amount. His legs felt heavy and numb. His sexual power for some

months had diminished greatly, and he had a slight degree of vesical weakness.

Examination (October, 1886).—The patient is a large man of muscular build and healthy appearance. His gait is heavy and a little uncertain; the feet come down heavily, the heels striking first. The muscles of the body look well developed. There were no changes discovered outside the nervous system. Urine, normal. The arms showed no signs of disturbance. Dynamometer, right hand, 40; left, 40. There was a slight degree of weakness in the legs, as tested by pushing against them. The electrical sensibility was lessened, the irritability increased. There were no qualitative electrical changes in muscle or nerve. The muscles of the lower extremities felt tense, and were over-irritable to mechanical as well as electrical stimuli. Blows upon them easily brought out welts of idiopathic contraction, and blows over the motor points caused lively contractions. The patella tendon reflexes were greatly exaggerated; there was ankle-clonus and paradoxical contraction. The triceps and wrist reflexes were very slightly exaggerated.

The patient stated that at night he suffered from trepidation of the legs, so that the whole bed shook. He also felt a stiffness in the legs, and suffered at times from crampy contractions in them. The plantar and cremasteric reflexes were exaggerated; the other skin reflexes normal. The lower limbs showed a considerable degree of tactile, pathic, and temperature anæsthesia, distributed in patches below the knees. There was no delayed conduction. Muscular anæsthesia was very well marked, as shown by posturing the limbs, moving to certain parts, and by his having both static and locomotor ataxia. There was great diminution of vaso-motor reflexes on scratching or pressing a dull point along the legs.

The patient has at times suffered from sudden severe startings of the whole body when about to go to sleep. He feels a sensation, beginning in the feet as a tickling, running up the body and ending in an explosive contraction of the muscles of the body. He has no eye-signs or symptoms whatever.

During the six months in which he has been under observation, there has been an improvement in the sensory symptoms; the motor symptoms improved for a time. Some atrophy has taken place in the legs.

Case VII. *Male, aged fifty; negative family history; no syphilis; alcoholic excesses; symptoms began eight years ago with pains; paræsthesia; ataxia; cramps and spinal trepidation; bladder trouble; no anæsthesia; ataxia and spastic symptoms marked.*—Christopher B——, aged fifty; male; Ireland; laborer.

In the details this case resembles Case V.

Case VIII.—Aged fifty-three. This patient was one of the best types of the disease, and a year ago was shown several times to my class as such. Unfortunately, his history has been lost, and the patient disappeared.

His symptoms were of long duration—over ten years. They were mostly confined to his legs. These were paretic, so that he could only walk with assistance, and then in a "scissors" fashion, on account of the spasm and adduction of the thighs. He suffered a good deal from pain in the back and legs. There was marked anæsthesia of lower extremities, ataxia, great exaggeration of reflexes, ankle clonus, spontaneous movements, some wasting, and loss of power. There was some ataxia in the arms. There was vesical weakness, sexual impotence, and spinal myosis, but vision was good. He had, in fine, spastic paraplegia plus ataxia, anæsthesia, pains, and slight disturbances of bladder.

Case IX.—Dr. Graeme M. Hammond's case. Male, aged forty-five; United States; married; pianomaker. Consumptive family history, chancre twenty-eight years ago; cough for two or three years; otherwise healthy until February, 1884; symptoms then began with sensation of coldness in toes, followed by burning pains, and then anæsthesia reaching to knees. He had to watch the ground when he walked, otherwise he would stagger and fall. In July, he noticed a weakness and uncertainty in the lower limbs, at the same time he began to suffer from painful contractions of the lower limbs. The motor and ataxic symptoms progressed until he had to use a crutch to help him in walking. Tight band feeling about the waist. He had burning, darting pains in legs. In September the arms became affected with cramps and darting pains. Loss of sexual power dates back two years. In September he began to lose control of vesical sphincter.

On examination in October, 1884, he was found to be emaciated, and signs of phthisis were present. There was paraparesis, though the patient could walk with help. Electrical reactions of muscles normal or slightly diminished. Superficial and deep reflexes greatly exaggerated, most in lower limbs. Ankle clonus. Tactile anæsthesia and analgesia in lower limbs below knees; upper limbs normal. Impotence; sphincters weak; eyes normal. No bladder troubles.

The symptoms gradually progressed, and he died of phthisis (syphilitic?) about a year after onset of the disease.

General course, of a subacute multiple neuritis, with ataxia, anæsthesia, and great motor irritability and weakness; or, in other words, *subacute locomotor ataxia and spastic paraplegia.*

Autopsy.—Lesions of syphilis in lungs, liver, etc. A peculiar vesicular degeneration of columns of Goll, very marked through whole length. Low grade of sclerosis of lateral columns and cerebellar tracts.

Prognosis of Progressive Spastic Ataxia.—The more superficial character of the lesions in spastic ataxia gives to it a more favorable prognosis than might be expected from its extent. In the present type we have only conducting paths involved, not centres, and hence the functions of life are less apt to be interfered with.

The lateral sclerosis, however, is liable in time to encroach on the mixed lateral column, and even the cornua; so also the posterior sclerosis may extend. Many cases have, therefore, run a course of but a few years. However, I think that, barring accidents in the prognosis, *quoad* life is better than in typical tabes. A patient of Strümpell's lived thirty years; one of mine has been doing professional work for ten years, and still is at it.

The Treatment of this trouble does not vary greatly from that of locomotor ataxia. I believe that in those cases in which excessive muscular work and exposure have been etiological factors, a very important thing is rest. Under this treatment I have seen remarkable amelioration in every symptom. The slight anæsthesia which exists can be made to disappear by the use of electricity. The trembling and trepidation of the limbs at night are often very annoying to the patient as well as being a disturbing element in the conjugal relations. Moderate doses of bromide relieve this.

I can strongly recommend the use of orthopædic appliances for giving support to the shaking knees and hips. Patients feel better and are even improved by the systematic, careful use of the faradic current, one of high tension, like Tiegel's battery or the static current being preferred. No class of patients, in my experience, have returned so persistently and faithfully for electrical treatment as those suffering with spastic ataxia, or spastic paralysis. A thorough course of anti-syphilitic treatment, using inunctions and occasional purges, should be tried if needed, and in later stages very large doses of the iodides are to be tried. In one case, undoubtedly syphilitic, this certainly did much good. The patient preferred iodide of ammonia.

Warm baths and cold douches are beneficial, but hot baths are dangerous. The stomach is a thing that must be attended to with great care. Rhubarb and soda is an excellent remedy for tabes.

Conclusions.—I. (*a*) There is a class of cases suffering from the milder symptoms of locomotor ataxia, such as ataxia, slight pains, paræsthesia, sexual and bladder

weakness, and also from symptoms of a spasmodic character, such as tremblings in the limbs, spontaneous movements, muscular stiffness, cramps, and some motor weakness. (*b*) There is also a class of cases in which the symptoms are primarily of a spasmodic character plus some paresis, ataxia, slight sensory troubles, and vesical weakness. In these two classes of cases the lower limbs are primarily and chiefly affected.

II. These cases form distinct clinical types which it is important to recognize both for prognosis and treatment.

III. The name given cannot yet be based on the pathological anatomy, since combined sclerosis is found in diseases running various courses. The nearest approach to accuracy would be to call it a "combined fascicular sclerosis," this representing the typical class. Clinically the disease may be known as progressive spastic ataxia or ataxic paraplegia.

IV. The typical anatomical changes consist of a degeneration of the thin, long fibre-systems of the cord, viz., the pyramidal tracts, the cerebellar tracts, the antero-lateral ascending tracts, and the columns of Goll. Being primary, this does not necessarily involve their whole length, and it is most marked in the dorsal region, where the mixed lateral columns often become involved. The disease is not always primary, but may originate from a dorsal myelitis or a syphilitic cord disease. It then runs a sharper course. The typical tri-fascicular lesion has in rare cases produced ataxia with a flaccid paralysis.

V. The disease has a long duration. It is less painful than true tabes, and it involves the eyes and the organic centres to less extent than does tabes dorsalis.

VI. It is diagnosticated by the presence of the spastic symptoms in conjunction with ataxia, by mild sensory disturbances, bladder and sexual weakness; by an absence of extensive involvement of organic centres until very late in its course. It has to be diagnosticated from pure tabes, primary spastic paraplegia, certain forms of chronic hydrocephalus, Friedreich's disease, chronic hydromyelus, and dorsal myelitis.

It is especially difficult and important to differentiate it from transverse myelitis, many cases of spastic ataxia having, I believe, been mistaken for that disease.

Acupuncture in Japan.—As practised by the Japanese acupuncturists, the operation consists in perforating the skin and underlying tissues to a depth, as a rule, not exceeding one-half to three-fourths of an inch, with fine needles of gold, silver, or steel. The form and construction of these needles vary, but, generally speaking, they are several inches long, and of an average diameter of one forty-eighth of an inch. Each needle is usually fastened into a handle, which is spirally grooved from end to end. To perform the operation, the handle of the needle is held lightly between the thumb and first finger of the left hand, the point resting upon the spot to be punctured. A slight blow is then given upon the head of the instrument with a small mallet held in the right hand; and the needle is gently twisted until its point has penetrated to the desired depth, where it is left for a few seconds and then slowly withdrawn, and the skin in the vicinity of the puncture rubbed for a few moments. The number of perforations range from one to twenty, and they are usually made in the skin of the abdomen, although other portions of the body are not infrequently punctured. The different locations to be punctured for various diseases are fixed by rules illustrated by diagrams, as in the *Jū-shi-kiyō*, a work now to be obtained at almost any of the second-hand book stalls. The diseases in which acupuncture is employed are very numerous and cover almost the whole range of medicine, but it is most successfully used in colic and other spasmodic disorders.—Dr. W. N. Whitney, in the *Sei-I-Kwai Medical Journal.*

RUBELLA (RÖTHELN: GERMAN MEASLES).

With a Report of One Hundred and Fifty Cases.[1]

By J. P. CROZER GRIFFITH, M.D.,

ASSISTANT TO THE PROFESSOR OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA; PHYSICIAN TO ST. CLEMENT'S DISPENSARY, PHILADELPHIA.

The recognition of rubella, although usually such an easy matter, is at times attended with difficulties so great that many physicians still refuse to believe in its independence. Even those who admit its existence give the most varied descriptions of its symptoms. Yet the earliest possible recognition of the disease in any case is often of the greatest importance to the well-being of the patient and of other individuals in the same house. The physician's error in diagnosis may be the means of spreading measles or scarlatina throughout a family or an institution.

I shall attempt, in considering the subject, to give, without much comment, the statements of many of the numerous writers whom I have consulted; and shall endeavor finally to draw from the literature, and from the cases reported here, some reliable conclusions concerning the description and diagnosis of the disease in question. Those who are interested in the matter will admit, I feel sure, that the confusion which exists is sufficient reason for another contribution on the disease.

The literature of rubella is already very extensive, and it has been impossible for me to make even an attempt at a complete bibliography. I shall append, however, a list of those writers (upward of 120 in number) whose publications I have been able to consult.

The cases upon which this paper is based number in all about 150. One-third of these occurred in my own practice, during the early months of 1886; the notes of 34 others, treated in the same year have been kindly furnished me by Dr. George E. Shoemaker; and Dr. J. H. Musser also has placed at my disposal those of nearly 70 cases observed by him in 1881, but never reported.

Name.—The disease has been variously named and misnamed in different languages. Among these titles we find rubeola, rubeola sine catarrho, r. notha, r. epidemica, r. morbillosa, r. scarlatinosa, rosania, roseola, roseola epidemica, rubella, rosalia, rosalia idiopathica, scarlatina morbillosa, scarlatina hybrida, morbilli scarlatinosi, rötheln, feuer masern, roséole, roséole idiopathique, rubéole, rougéole fausse, German measles, French measles, false measles, bastard measles, hybrid measles, bastard scarlatina, etc.

The term "rubeola" is largely applied to it in Germany and in France (rubéole); but as it is the name often used for measles in English-speaking countries, it is best to avoid it. There is no reason why we should adopt the German word "rötheln," which is usually mispronounced, and for whose proper pronunciation, indeed, we have no equivalent vowel-sound in English. "Roseola" is a generic word whose employment here only adds to the confusion. As it seems best, then, to use some other name, I shall employ the term "rubella," advocated by Veale in 1866, adopted by Squire, and used as the reference-word in Dunglison's "Medical Dictionary." This word, too, being a diminutive of rubeola, expresses at once the usually slight import of the disease, and its relationship to measles—akin to that existing between varicella and variola.

Historical Sketch.—How long rubella has been in existence is impossible to determine. Some writers are of the opinion that it was known to the Arabian physicians under the name of "Hhamikah," and by them considered a form of measles. Descriptions of a variety of this disease, which it is claimed was identical with rubella,

[1] I have made no reference anywhere to the valuable paper of Atkinson (American Journal of the Medical Sciences, January, 1887), because my own paper had been completed before his appeared.

were also given by Ingrassias, Ballonicus, and Sennertus in the seventeenth century. But up to the accounts published in Germany by De Bergen in 1752 and Orlow in 1758—unless we accept the publication of F. Hoffmann in 1740—there seems to have been no attempted recognition of a third distinct and specific eruptive fever different from both measles and scarlatina.

Germany.—Taking a hasty review of the history of the disease in Germany, we find a report by Selle, in 1780, of a very malignant epidemic. Ziegler in 1788, Formey and Fielitz in 1796, Sprengel, Stark, and others also maintained its specific nature and reported epidemics. It was generally considered a serious and often fatal malady. Formey stated that between the years 1784 and 1796 1,180 persons died of it in Berlin; while during the same interval there were but 203 deaths from scarlatina and 103 from measles. The descriptions given by these authors vary considerably. The writer last quoted reports the disease as beginning in the throat, where a white coating was often found. Vomiting and severe nervous symptoms—as coma and delirium—were not uncommon. Selle describes the eruption as consisting of miliary pustules. Others, again, write of a universally diffused, flaming-red rash, followed by a desquamation of large scales, and sometimes by dropsy. There were, however, many physicians who did not believe in its independent existence. Göden (1822) confounded it with scarlatina; Jahn (1835) denied its existence entirely; Hufeland, Frank, Reil, Heim, and others considered it a form of scarlatina, although Heim gave a description of the eruption much as we now find it in rubella. This opposing view gained the upper hand for a number of years. The fact nevertheless remained that there did exist an eruptive fever having a benign course and a characteristic eruption, and which could not be classified with either measles or scarlatina. To get rid of this stumbling-block, Hildenbrand, as early as 1825, and Schönlein, in 1832, had maintained that rubella was a hybrid of the other two fevers. This opinion, or the view of the disease as a transitional form, gradually supplanted other theories. It was shared by Geertsema (1821), Busche (1841), Paasch (1854), Gelmo (1858), and many others. Many interesting instances were reported, seeming to uphold it. It was claimed that the malady prevailed at the same time with both scarlatina and measles; or while an epidemic of the one was on the wane, and one of the other increasing in severity. Epidemics of rubella frequently occurred, too, in localities lying between two districts, in one of which measles was to be found, and in the other scarlatina. I have only space to quote from two of these publications. Paasch attended in families where typical measles first appeared; then cases characterized by very little fever, an eruption of small red spots, and slight sore throat; and, following these, others of an undoubtedly scarlatinal nature, accompanied by marked anginose symptoms. One of the most interesting accounts, purporting to show the influence of scarlatina and measles upon each other, and the non-existence of rubella as a specific disease, is that by Gelmo. He reports epidemics of the first two diseases, occurring at various times between the years 1848–53, inclusive, and describes cases illustrating a transitional form between them. In 1853, for example, the last patients of an almost exhausted epidemic of scarlatina showed an eruption which was but poorly developed, consisting of minute spots or of patches the size of the hand. The incoming epidemic of measles, which immediately followed, presented, besides the ordinary catarrhal symptoms, inflammation of the tonsils and a confluent redness of the whole cutaneous surface. The cases of measles, which were observed later, ran a normal course.

The general opinion among physicians in Germany continued to tend toward the entire rejection of rubella as a disease *sui generis*. This was the view of Canstatt, Hebra, Gintrac, and others. But, in spite of all opposition, there were still many believers in the specificity of the third exanthema. Among these were Behrend (1828), Wagner (1834), Meissner (1844), and as time went on others were added to them. After 1860 the independent existence of rubella was maintained in Germany by Mettenheimer, Thomas, Hennig, Thierfelder, Vogel, Wunderlich, Lindwurm, Arnold, Gerhardt, Steiner, Kuster, Roth, Emminghaus, and many others, with Nymann in Russia, and De Man in Holland. This view is now held almost without exception. Strümpel says that the existence of rubella can only be denied by those who have never seen it.

England.—In England the question received but little attention until later years. Tripe claims that Fothergill in 1754 described rubella in his essay on a certain kind of malignant sore throat. A perusal of this paper renders it more than probable, however, that it was a form of scarlatina. Willan in 1808, and Bateman in 1813, described a roseola, and also a rubeola sine catarrho, which did not protect from measles. But Maton in 1815 was the first to recognize rubella as an affection distinct from either measles, scarlatina, or roseola. Nevertheless, the view that it was only an anomalous form or a hybrid prevailed in England also until 1840, when Paterson maintained that it was a disease *sui generis*, and gave a description of it, though as he described it the affection was certainly more severe than it now is. Tripe agreed with this in 1852, and Balfour in 1857. Later there prevailed a difference of views. Copland in 1858 claimed that it was a hybrid, and this was the belief of Aitken. Reynolds' "System of Medicine" (second edition, 1870) contains no notice of it; Watson scarcely mentions it. On the other hand, it is firmly believed in by Veale (1866), Murchison (1870), Liveing (1874), Dunlop (1871), and others. Among the numerous reports of epidemics during the last decade may be mentioned those of Cheadle (30 cases), Shuttleworth, Douglass (50), Tonge-Smith (145), Wilson, Dukes (63), and others; and that of McLeod from Calcutta. The specific nature of the disease is now usually admitted by English writers.

France.—In France the disease received less attention than in Germany. Its existence as an independent affection was disputed in the early part of the nineteenth century. Rayer in 1826 confounded it with roseola, and denied its specific character. Alibert (1832) recognized in it a distinct disease; called it "roséole idiopathique," in contradistinction to symptomatic roseola; and described its symptoms nearly as we know them. Barthez and Rilliet, in their edition of 1853, classified it with roseola; later, in 1861, they appear to recognize its independent nature, and say that it bears the same relation to measles as varicella does to variola. From this time the majority of writers in France, as in Germany uphold the distinctiveness of rubella. Although it is denied by Thore, it is maintained by Danis, Trousseau, Roger, and Damaschino, Delastre, and others.

Italy.—My search after the history of rubella in Italy has been almost totally barren of success. In the "Diction ary of Medical Terms," by Longhi and Tirinanzi (1882), no mention is made of it as a distinct disease. That it is, nevertheless, recognized by some modern writers is proved by the paper of Cuomo in 1884; but with this exception I have found almost no reference to it.

America.—Homans, of Boston, was the first to recognize rubella in this country, having seen and described cases in 1843. Cotting read a paper on the disease in 1853, and published an account of a series of cases in 1871. Caleb Green, too, in the same year stated that he had witnessed an epidemic. In 1874, J. Lewis Smith brought the disease prominently before American physicians, and since that date a great number of communications have been published. Many epidemics of considerable size have been reported; among them those of Hatfield (110 cases), Park (over 100), Earle (120), Edwards (166), and Kingsley (21).

Rubella an Independent Disease.—We have seen, then, how rubella, at first looked upon with suspicion or utterly denied being, has at last won an established place for itself, although there are still some quite recent writers who are disposed to deny its separate existence. Henoch, for example, almost repudiates it; Fagge, in his "Practice of Medicine," recently issued, says that the only reason for the admission of rubella as a distinct disease is that "it explains the occasional supervention of what appears to be a second attack of measles in the same individual. But," he continues, "the importance of this argument may be easily overrated." Goodhart thinks it can be a hybrid as well as a distinct disease. Descroizilles does not recognize it at all. Two of those partaking in the discussion at the International Medical Congress in 1881 (Stewart and Oxley) did not believe in it, and I have met with several other dissentient views in the literature.

It would seem, then, not unnecessary to formulate some of the propositions upon which the theory of the independence of rubella rests:

1. It is an epidemic and contagious eruptive fever, and not a simple affection of the skin.
2. It prevails independently of the existence of measles or scarlatina.
3. Its incubation, invasion, eruption, and symptoms differ materially from those of either of the other two fevers.
4. It attacks indiscriminately and with equal severity both those who have had measles or scarlatina and those who have not; nor does it protect in any degree from either of these diseases.
5. It never produces anything but rubella in those exposed to its contagion.
6. It occurs but once in the same individual.

Some of these propositions will be admitted without dispute, and do not need proof; others will be discussed incidentally later in the paper. The admittance of the truth of the 4th is alone sufficient to establish the existence of rubella as a distinct disease, unless we admit that measles and scarlatina are very likely to occur a second time in the same person. But this is contrary to the universal experience and belief. Were it a hybrid of the two, or a variety of either disease, so modified that it could not protect *fully* from the typical disorder, we would with reason expect, on the one hand, that rubella would be more severe in those individuals who had never had measles or scarlatina; and, on the other hand, that the previous occurrence of rubella would greatly modify the virulence of the other affections. But it is, I think, almost uncontested that the three diseases have no protective power whatever upon each other.

Again, the disease often prevails at a time when both or one of the other two are not epidemic. This statement expresses the views of those who have studied rubella excepting the older writers, who certainly often confounded the three affections.

That rubella does frequently occur in those who have had measles and scarlatina is proved by the evidence of various writers, as seen in the following statement:

Of J. L. Smith's 48 cases, 19 had had measles; of De Man's 33 cases, 10 had had measles, 4 scarlatina; of Thierfelder's 45 cases, 22 had had measles, 5 scarlatina; of Hatfield's 110 cases, many had had measles and scarlatina; of Shuttleworth's 27 cases, 15 had had measles and scarlatina, and 5 had both diseases in later years; of Klaatsch's 22 cases (first epidemic), 11 had had measles; of Klaatsch's 40 cases (second epidemic), most had had measles; of Dukes' 88 cases, 61 had had measles; of Cheadle's 30 severe cases, 22 had had measles.

Quite a number of the cases to be reported in this article had previously had measles, or developed it afterward.

It has been strongly urged against the existence of this fever that physicians are not agreed as to its symptoms; and that the severe disease described by the earlier writers, and even by Copland, Aitken, and others, is quite different from the trivial affection as it is now usually seen. Of the rubella of the older writers, Thomas says: "It is probable that much that has been described under this name [rubeola] was nothing more than measles or scarlet fever." This remark applies with equal truth, I think, to some of the severe cases and epidemics more recently reported. It is also to be borne in mind that rubella, like other contagious diseases, may vary greatly at different times and places; and, further, that very anomalous cases may occur. Still another possibility exists, that, as Klaatsch and some others believe, the disease has become gradually modified, and much less severe, during the time which has elapsed since the first descriptions of it were published.

Etiology.—There is abundant proof that rubella is *contagious*, and this fact is now very generally admitted. It has been, however, doubted by many. Kassowitz, in his earlier writings, and Steiner deny it altogether; Slagle questions it; and De Man, Picot, Mettenheimer, Arnold, and Lindwurm only think it probable. Walch believes it may arise spontaneously, and says that epidemics of it appear in Malta as soon as the rainy season sets in. As to the *degree* of contagiousness, Thomas thought it somewhat less than that of measles; and Tonge-Smith, Liveing, Bourneville and Bricon, Hardaway, and others are of the same opinion. Squire, Chadbourne, and J. L. Smith say the disease is feebly contagious. Klaatsch thinks it is more so in some epidemics than in others; and Jacobi and Dukes consider it very contagious. My own experience leads me to believe that the contagious nature of rubella is very decided. Out of about 100 cases in a "Home" where I attended, 37 took the disease in spite of the most prompt and careful isolation. Out of approximately the same number in another institution, 26 were attacked. Thomas, Roth, Veale, and others think the disease is probably *infectious* also; Emminghaus believes that this is proved by cases reported by Balfour. Edwards states that the origin of many of his cases could be traced to infection from the bunks in ships.

Rubella occurs chiefly in *epidemics*, and most frequently in winter and spring. J. F. Meigs stated[1] that he considered it rather epidemic than contagious. This is, too, the opinion of Slagle. Liveing and Edwards deem it more prone to be so than are either measles or scarlatina; and Thomas emphasizes its epidemic nature. Whether it is a *cyclic* malady, as Thomas thinks probable, with a period of some years between its appearances in the community, can only be determined by further investigation.

Regarding the *stage* at which rubella is most easily communicated, there is little known, and opinions differ. Thierfelder believes it to be most contagious during the healing stage. Squire thinks it can be communicated before the rash appears, and for a month after this date. The spread of the disease throughout an institution, despite prompt isolation of the affected children—as in some of my own cases—proves that it is certainly contagious in the early stages. The nature of the *materies morbi* is unknown. The manner in which it is conveyed is probably by exhalations from the skin and from the breath, as in the case of measles. The discovery by Edwards and Formad of micrococci in the blood of some cases is interesting, but, I believe, has not yet been confirmed. There is no reason to believe that rubella ever imparts any disease but itself; and it is almost universally admitted that it occurs but once in the same individual. Trousseau, Picot, and Bourneville and Bricon are among the very few disposed to deny the latter statement; and Trousseau says, too, that an attack may be repeatedly induced by high temperature and by copious perspiration.

Sex appears to be without influence upon the occurrence of the disease.

---

[1] Personal communication.

Rubella is an affection of *childhood*, occurring especially between the ages of five and fifteen years. I have seen it in children under two years of age and Scholl reports it in an infant a few days after birth, the mother having had it two months before. But early infancy is usually exempt. Adults are also attacked, though comparatively seldom.

Of 55 cases reported by Thomas (1868), 2 were adult; of 22 cases reported by Thomas (1872), 1 was adult; of 42 cases reported by Emminghaus, 2 were adult; of 19 cases reported by Roth, 1 was adult.

Although there were many adults connected with the institutions for children in which one hundred of the cases here reported occurred, yet but one of the number was attacked.

Seitz reports the disease in a woman seventy-three years of age.

Incubation.—The larger number of my own cases occurred in an epidemic in one of the "Homes" already referred to, and this circumstance offered excellent opportunities for the careful study of the disease. The first case was that of a child who, to my certain knowledge, had been very ill with measles two years previously. While temporarily absent she was taken ill with rubella, and was one of the children most severely attacked. The rash appeared on February 24, 1886, on which day she returned to the "home." On March 1st, *i.e.*, five days after the first exposure, 2 children exhibited the eruption; and on the 3d it appeared in 3 others. On the 4th, *i.e.*, eight days from exposure, 7 more children were affected; on the 5th, 2; on the 6th, 5; and on the 7th, eleven days from the first case, 7. From this time on fresh cases appeared almost daily, but it was impossible to determine from which patient the disease was contracted. Isolation was practised at once in every instance. Contagion from any other source outside was of the greatest improbability. In this series, then, the shortest period of incubation was five days, and 28 cases developed within eleven days. Most of the cases under the care of Dr. Musser occurred in a Home for boys. One of the inmates who was employed in the city during the day (he was the only one ever leaving the Home) contracted rubella there, and six days from the first appearance of the rash upon him the first of the other children was taken sick. Here the period of incubation was almost certainly six days. There remains, nevertheless, an element of doubt, since the disease may be contagious before the eruption appears.

The incubative period occupies a much longer time according to many writers, and I have indeed seen cases in other epidemics where this stage was undoubtedly much more prolonged. Glaister gives the duration of incubation at four to five days, or longer; Robinson, six to seven days; Pollock, six to sixteen days; Edwards, six to twenty-one days (average, ten days); J. L. Smith, seven to twenty-one days; Bourneville and Bricon, eight to ten days; Squire, eight to twenty-one days (usually fourteen days); Hatfield, in two cases, definitely, ten days; Steiner, ten to fourteen days; Cheadle, definitely, eleven to twelve days, in two cases; Dukes, twelve to twenty-two days (average, fifteen to sixteen days); Duckworth, in one case known to be sixteen days; Cuomo, never less than seventeen days; Cullingworth, Balfour, and Tonge-Smith, two weeks; Goodhart, Jacobi, Hardaway, Mettenheimer, and Thierfelder, two weeks or longer; Gerhardt, Kassowitz, Emminghaus, Picot, and Eichhorst, two to three weeks; Thomas, Earle, and Klaatsch, two and one-half to three weeks; Cotting, about three weeks.

The above list has been made thus extended in order to show the very varying duration of the period. This is, indeed, one of the diagnostic marks of the disease, in contradistinction to the fixed period of incubation of measles. The greater number of the writers quoted state it to be fourteen days or longer; but it may certainly last a very much shorter time.

There are no symptoms appearing regularly during the stage of incubation. Squire states that some complaint of the throat is occasionally made, and epistaxis and enlargement of the post-cervical glands may be noted.

Invasion.—Many of the cases reported here exhibited no prodromes at all. In a large number, however, slight symptoms were observable, not more than twelve hours before the rash made its appearance. There were malaise and generally decided drowsiness, and the eyes frequently became red and watery or had a heavy look. Sneezing was noticed, and there was often a slight cough. One case exhibited prodromal symptoms twenty-four hours, and another forty-eight hours, before the eruption appeared. The temperature during this stage was not recorded.

The testimony of the large majority of writers is, either that there are no prodromal symptoms whatever, or that they usually last but a few hours or a day and are of slight import. This is the opinion of Thomas, Klaatsch, Liveing, Hardaway, J. L. Smith, Brodie, Squire, Maton, Cotting, Bristowe, Day, and many others. Park, in over 100 cases, detected no symptoms during the invasion. Earle, in 120 cases, saw no prodromes in children, but frequently observed them in adults. Tonge-Smith, in 145 cases, found them absent or slight. The number and nature of the slight prodromal symptoms are variously described; but, from a comparison of very numerous published reports, it would seem that the symptoms which may be expected in a normal case are malaise, often slight cough, suffusion of the eyes, with perhaps some lachrymation, probably some coryza, sometimes pains in the limbs, drowsiness, at times hoarseness, sore throat often, enlargement of the glands at the back of the neck and behind the ears, possibly an elevation of temperature of 1° to 2° F., occasionally nausea, and some œdema of the face. But any or all of these may be wanting.

A number of writers differ from those mentioned in extending the usual duration of the stage of invasion. Many of these, however, admit that the prodromes may be absent or slight; while some of those already quoted concede the possibility of their lasting longer than twenty-four hours.

McLeod says that this stage lasts twenty-four to thirty-six hours; Murchison, that it may continue forty-eight hours or less; Binns puts it at two days; Mettenheimer, Henderson, Kingsley, Thierfelder, Emminghaus, Roth, one to three days; Copland, Cuomo, and Cheadle, two to three days; Cullingworth and Edwards, three days; Paterson and Aitken, three to four days; Lindwurm, four days; Hemming, a few hours to five days; Balfour, two to six days; and Claussen says that in some cases there is malaise for six to seven days.

The stage of invasion may be, then, without question prolonged, or its symptoms unusually severe; but, from the overbalancing mass of evidence upon the other side, I am inclined, with Hardaway, to adopt the view of Thomas—viz., that "a prodromal stage of more than, at most, half a day . . . constitutes an anomalous case."

Other prodromal symptoms are occasionally seen, but must be called unusual. Vomiting occurs rarely, according to J. L. Smith, Murchison, McLeod, and Emminghaus. Kingsley says it usually precedes the rash. Cuomo reports its presence in anomalous cases. I have seen it in but two instances. Convulsions are reported by J. L. Smith, Edwards, Lindwurm, Cuomo, and Alexander. Delirium, by Hardaway, Cuomo, and Edwards. Urticaria, by Cullingworth. Hemorrhages from the eyes and ears, by Prioleau. Epistaxis, by Edwards. Dizziness, by Squire. Fainting, by Mettenheimer. Croup-like attacks, by Balfour. Intense headache, by Cuomo. Nymann noticed rigors in 19 out of 119 cases. Emminghaus says they are found but seldom. This author and Thierfelder report the occurrence of a slight, cloudy redness immediately preceding the ap-

pearance of the rash; and Edwards reports erythema in 4 cases, and Cuomo in 7.

Eruption.—Following the slight prodromal symptoms, or without these, and in the midst of health, the eruption of rubella appears. Very often, as Thomas observes, the child is found covered with it after the night's sleep. There is some difference of opinion as to the part of the body which it attacks first, and the order in which it involves other parts. Most writers are agreed that, as a rule, it appears first on the face and spreads with great rapidity over the rest of the body (a few hours to a day), attacking the legs last. This is the opinion of Thomas, Emminghaus, Squire, Picot, Rilliet and Barthez, Mettenheimer, Klaatsch, Bourneville and Bricon, and many others. Liveing and Morris claim that its first appearance is on the back and chest; Day, Murchison, and Balfour, that it is to be first seen on the breast and arms; and Paterson and Copland, that it develops all over at once. Park says that the eruption is often to be seen on the roof of the mouth before visible on the skin, and then appears on the neck. In the few cases in which I have been able to detect any sequence in the appearance of the rash it was visible first upon the brow and over the body of the lower jaw, thence shading off upon the neck. Indeed, in some cases it could be found at no time elsewhere. It is possible, as Emminghaus claims, that such cases are explained by the unobserved existence of the rash for a few hours upon other parts of the body. Heim, however, was of the opinion that there could be a local eruption, and there is reason to believe that this may occur. Reed described a case in which the rash was visible only on the tonsils and palate. In one of the cases included here it could be seen only upon the face and neck, although the attending symptoms were quite severe. In another instance the rash could be found only during a few hours and upon the brow, in spite of most careful inspection of other parts of the body.

The entire cutaneous surface may be attacked. J. L. Smith and Emminghaus except the soles and palms; but Thomas, Roth, and others mention its occurrence there, and some of the cases in this report exhibited it in these situations. Tonge-Smith claims that the rash invades the oral circle, and that this distinguishes it from scarlatina. Pathologically the eruption of rubella is defined by Thomas to be a hyperæmia of the papillary body and upper layer of the corium. In a typical case, such as were found in numbers in the epidemics reported here, it consisted of small irregularly shaped spots of pin-head to split-pea size, of a peculiar pale rose-tint, more or less sharply defined, and somewhat elevated both to the touch and to the sight. The spots are not arranged in groups, as in measles, are widely distributed, and more or less closely placed. They are usually discrete and separated by larger or smaller areas of healthy skin, but show a tendency to become confluent on certain parts of the body, particularly on the face and those parts kept warm and under pressure, as are the nates and the flexor surfaces of the thighs in bed.

On the trunk, and especially on the back, the rash is usually paler or of a brownish-red color, fine, and very thick. On the wrists and ankles, and sometimes on the fingers and toes, the isolated papules are usually very evident. In this connection, to illustrate the influence of pressure, I may mention a case in which the eruption was particularly well developed in two circular bands, one around each leg, above the knee, where the garter had been worn. A similar band-like eruption upon the legs is mentioned by Klaatsch.

The above description is essentially that given by the majority of modern authors. But there is no doubt that the eruption is exceedingly variable—"multiform," as Duhring names it—and many of the descriptions vary accordingly. Not only does the rash differ in different epidemics, but in different cases in the same epidemic. Even in the same person two types of eruption may appear, as will be described later.

Heim says the rash resembles the appearance produced by dotting moist white paper with a quill pen dipped in red ink. This description is adopted by Paterson. But we can scarcely take into consideration the accounts of the rash given by the earlier writers, since it is very certain, as insisted upon by Thomas and Bourneville and Bricon, that the disease reported by them was very different from rubella as we know it.

In examining more particularly what has been said by modern writers upon the individual features of the rash, we find that Thomas describes its color as a pale rose-red, not so bright as the red of severe scarlatina, nor having the bluish-red tint of intense measles. Shuttleworth calls it a brownish-red. Aitken states that it is more elevated than in measles; Mettenheimer, that it is confluent upon the cheeks. The development of vesicles is extremely rare. I have found it noted by Curtman, Cuomo, Thomas, Hardaway, and Copland. Thomas, Gerhardt, and others say that the spots of rubella possess either smooth or indented edges, and are in the latter case often connected with each other by delicate processes. Emminghaus and Cuomo speak of a marbled appearance of the skin, and of small, delicate blood-vessels sometimes to be seen in the healthy portions. Petechiæ have been described by Dunlop and Cheadle, and a purpuric rash in one case by Glaister. Cheadle also says that the rash is darker, more purple, and more papular than in measles; but the epidemic which he reports was in many ways anomalous. Claussen noticed that upon pressing upon the papules there was a sensation as of small shot beneath the skin. In this connection I may report an analogous case. The eruption covering the child on the first day was composed principally of *annular spots*, from the size of a pea to that of a silver three-cent. piece, of a pale rose-red color, with a distinct yellowish tinge in the centre. In most of these macules a distinctly hard, small, shot-like body could be felt beneath the skin. The annular appearance was very marked. Being somewhat at a loss regarding the exact nature of the eruption, I asked Dr. Van Harlingen to see the case with me, which he did upon the following day. Within the twenty-four hours, however, the rash had altered its nature so completely that there could be no longer any doubt that the disease was rubella.

According to Rilliet and Barthez, the rash may disappear and again appear upon the same day or later. I have seen one instance in which it was invisible during one day and returned. This phenomenon is, of course, not to be called a "relapse" of the disease.

In another patient of Dr. Musser's the rash could at first only be kept upon the cutaneous surface by the repeated use of hot baths. The symptoms in this case were severe.

There is some difference of opinion concerning the degree of elevation of the eruption. Thomas, Emminghaus, Mettenheimer, Wunderlich, Roth, and others say that the spots are slightly elevated. Hardaway, Cuomo, Duhring, and others describe the rash as macular. The multiform nature of the eruption accounts for these differences.

From a study of the cases reported here, there seems to me to be two easily recognizable *types* of variation from the character of the eruption in a normal case:

1. An eruption in which the spots are for the most part nearly or fully the size of a split-pea, more or less grouped, and, in fact, having the greatest resemblance to measles.

2. A rash which is confluent in patches or universally, not elevated, and which produces a uniform redness, closely simulating that of scarlatina. Very careful examination will often reveal a few papules amid the general diffuse redness. These can be best seen between the brows and on the wrists or fingers.

Other cases exhibit all gradations from the normal type toward either of these extremes. The rule may perhaps be formulated, that the more macular the rash, the

greater the disposition to confluence ; and the more distinctly papular, the greater the tendency to form measle-like groupings.

The existence of a scarlatinal and of a rubeoloid form of eruption in rubella forced itself upon my attention before reading the reports of somewhat similar observations by a number of writers. Harrison has remarked this same condition of affairs. Klaatsch maintains that an erythematous blush may extend over the skin between the spots, so that at first sight the disease resembles scarlatina. Copland says the eruption is usually discrete ; but in some cases is more diffuse, and may then be readily mistaken for scarlatina. He claims, however, that this redness fades after two days, while the spots remain. I have never observed any fading of the general redness in my own cases. Goodhart describes the rash as sometimes resembling measles and sometimes scarlatina ; while Byers reports a case in which it was scarlatinal in some parts of the body and rubeoloid in others. Picot and Henderson make a similar observation in a greater number of cases ; and Ladell reports three such, two of which developed scarlatina about six months later, and the other measles. Kassowitz states that the spots are sometimes large, elevated, and confluent, as in measles. Dukes says the rash may be a diffuse, rosy redness, or may be in spots as in measles. Murchison and Liveing state that the rash is in spots, but that these may coalesce and closely resemble scarlatina. The same observation is made by Tonge-Smith, who describes the eruption, which is at first in spots, as becoming "blurred" on the second day, and as then indistinguishable from scarlatina. The change in appearance produced by this "blurring" he compares to the effect produced by rubbing with the dry hand a series of dots made upon a slate with an ordinary slate-pencil. Hatfield describes an epidemic in which many of the cases could not be distinguished from measles, while the eruption in other patients was almost exactly like that of scarlatina. Kingsley states that the rash is often confluent, as in the latter disease ; and D'Espine, that it is often impossible to distinguish rubella from measles. J. L. Smith, too, writes that, although the rash is usually more like measles, an erythema sometimes extends over the skin, producing an appearance like that of scarlatina. One case he would have considered to be mild scarlatina, had he decided only from the appearance of the rash. A very similar case occurred in my own practice. Although the eruption was at first macular on the face, yet on the second day it so closely resembled scarlatina that I was unable for several days to make a diagnosis. Not a single macule or papule could be found in the general scarlatinal blush which covered the whole body. The subsequent course of the disease proved that it could only have been rubella, and a short time afterward the brother of the patient was attacked. I have indeed repeatedly observed the change on the second day from the papular to a confluent, not elevated form, as described by Tonge-Smith.

Writers have been quoted here at perhaps too great a length ; because, in spite of the facts, we find some of our best modern text-books (as Thomas in Ziemssen's "Cyclopædia," Bristowe, and others) stating or implying that rubella has no similarity to, and can scarcely be mistaken for, scarlatina. Bourneville and Bricon say it is astonishing that they could ever be confounded. It is, of course, generally admitted that rubella has usually a much closer likeness to measles. Thomas, while denying that the disease has any likeness to scarlatina, hints at the possible existence of another exanthem bearing a resemblance to scarlatina. Filatow, of Moscow, has recently gone further than this, and makes two distinct species of rubella, which he calls *rubeola scarlatinosa* and *rubeola morbillosa*—the latter being the one which we usually see, the typical rubella. He claims that they are entirely distinct affections, but does not offer sufficiently convincing proof of this. The evidence already given here shows, I think, that they are produced by the same contagion, and are consequently the same disease.

Other classifications of the eruption are sometimes made. Thomas, for example, describes three forms, depending on the size of the spots ; Emminghaus speaks of a confluent and a discrete form ; Nymann and Klaatsch, of a punctate variety and of one with large spots.

Although, then, there is a definite normal type of eruption in rubella, the numerous variations from this teach us that we must keep in memory the words of Maton, in 1815, the first English writer to recognize the disease : "But, after all, the true distinctions of this disease are, in my opinion, to be founded on the more general and constitutional circumstances."

Concerning the time the eruption persists upon different regions of the body, Thomas writes that it happens with tolerable frequency that the maximum of the development of the eruption on different parts occurs at different times. The rash is often at its height upon the face, neck, and upper portion of the trunk before it has appeared on the extremities ; and when, after twelve to twenty-four hours, the acme is reached in the latter regions there remains often but little to be seen on the parts first affected. The duration of the most marked development of the eruption on any one locality is from a few hours to half a day. Hardaway goes further, and claims, with Emminghaus, Roth, and Mettenheimer, that this sequence of the maxima of the eruption upon different parts of the body is one of the safest diagnostic signs of rubella. The same feature has been noted by Squire and by Gerhardt. According to Emminghaus, this probably explains the difference in the views of writers concerning the seat of the first appearance of the eruption—*i.e.*, the rash may have already disappeared from the face when it is found apparently first upon the breast or elsewhere.

My own experience leads me to agree with Thomas, that this sequence of the maxima "happens with tolerable frequency." But I am not able to admit it as an important and safe diagnostic sign. I have nearly as often observed that the rash persisted with equal intensity on the face while it spread to the rest of the body, so that it could be said to reach its acme everywhere *upon the second day*. It then grew rapidly paler, either beginning on all parts at the same time or fading first from the face. Frequently it seemed to persist longest on those parts which had been the most affected, and was thus often visible on the face and nates after other regions were quite free of it. I have seen one instance, too, in which the order of the shifting maximum of Thomas was preserved, but was very much prolonged, the rash not reaching its acme upon the feet until the third day.

It is safe to infer that this absence of a universal maximum of the eruption has certainly not been confirmed by the greater number of writers, else some mention would probably be made of it, and we would not read that the "eruption reaches its height" on the *second day*, as stated by Picot, Copland, Kingsley, Bristowe, Shuttleworth, Tonge Smith, Bourneville and Bricon, and others ; or on the *third day*, as Cheadle claims. These differences of opinion only show the tendency of the disease to vary.

The total duration of the rash upon the body is variously stated. It is given at half a day to one day (seldom three), by Gerhardt ; one to two days, by Troussean ; two to three days, by Thomas, Alibert, Rilliet and Barthez, and Bourneville and Bricon ; two to fifteen days, by Edwards ; three days, by Claussen and J. L. Smith ; two to four days, by Kingsley and Emminghaus ; three to four days, by Maton and Picot ; four days, by Hatfield ; one to five days, by Klaatsch ; four to six days, by Balfour ; four to five days (in bad cases, six to ten), by Copland and Aitken ; five to seven days, by Liveing ; and in one case, fourteen days, by Alexander.

From a careful review of my cases, I find the rash

lasted usually only two or three days; less often, four or five days. In some cases it had disappeared entirely within the first twenty-four hours.

Combining this with what seems to be most trustworthy from the various published accounts, its average duration may be said to equal three to four days; although it very often lasts a much shorter time, and may continue even longer.

(To be continued.)

COCAINE AS AN AID TO DIAGNOSIS IN CASES OF NEURALGIA AND NEURITIS.

By M. ALLEN STARR, M.D., Ph.D.,

PROFESSOR OF NERVOUS DISEASES, NEW YORK POLYCLINIC.

In cases of neuralgia or of neuritis, and also in cases of reflex tic convulsif dependent upon irritation of a sensory nerve, it is always desirable to localize accurately the part of the nerve which is affected. This is not difficult in many cases where points of tenderness in the course of the nerve or along its trunk can be discovered. But in some cases the existence of tender points is not sufficient to determine the seat of the molecular or inflammatory change. Thus, in cases of sciatica it is often important to be able to ascertain whether the condition present is a neuralgia or neuritis of the peripheral portion of the nerve or of the central portion due to pressure within the pelvis. And in cases of trigeminal neuralgia affecting a single branch of the nerve, it is an advantage to establish the fact that there is no lesion in the bony canals through which the branches pass, and no disease in the Gasserian ganglion. And in cases of facial tic it is exceedingly important to ascertain from which branch of the trigeminal nerve the irritation proceeds which produces the reflex spasm.

In cases of these various kinds hypodermatic injections of twenty minims of a four per cent. solution of cocaine may be used with advantage as an aid to diagnosis. For it is a law of physiology that irritation at any part of a sensory nerve sufficient to produce pain will result in the pain being felt, not necessarily at the spot of irritation only, but also at the peripheral termination of the nerve. When the ulnar nerve is compressed at the elbow the tingling is felt in the fingers. But cocaine placed around a nerve interferes with the conduction of impulses from the parts lying on the distal side of the point affected by the cocaine.

Supposing now that the case under observation is one of sciatica due to a localized neuritis of unknown seat, if the inflammatory exudation compressing the nerve is along its course in the thigh or leg a deep injection of cocaine at the point of exit of the nerve from the sciatic notch by suspending all transmission of sensations from the affected part will stop the pain. If, however, the lesion is within the pelvis, the injection will have no effect, for the pain will continue to be felt in the thigh and leg even though these parts may be anæsthetic from the effect of the cocaine. The injection may, therefore, be of considerable service in locating the lesion. This is of some practical importance, for if a lesion is high up on a nerve counter-irritation applied along its peripheral distribution will have no effect; while if the lesion is peripheral such treatment is indicated.

In a case of facial tic affecting the entire right side of the face the same procedure has been of service, for it was impossible to ascertain the source of irritation in the trigeminal nerve by ordinary examination. Deep injections of cocaine at the point of exit of the infra-orbital branch of the nerve, however, arrested the spasm, and proved, first, that the spasm was reflex from a sensory irritation; and secondly, that that irritation was limited to this branch of the trigeminal nerve. Division of the nerve at this point was followed by recovery from the tic.

In local neuritis and in tic convulsif the procedure has been of service. Whether it will prove of equal use in neuralgiæ dependent probably on diffuse molecular changes rather than upon a local lesion, is questionable. But in the cases in which the question arises, whether the condition is one of neuritis or of neuralgia, and in which the usual differential diagnostic symptoms fail, the method may prove of service; for a cessation of pain when injections are used at a definite part of the nerve would indicate a local affection of the parts lying peripherally from the point of injection—that is, a neuritis, rather than a neuralgia, which is usually diffuse or due to central changes. Further trial is, however, necessary to establish any definite use in this connection. In the localization of lesions in neuritis it is a procedure which is of real service.

THE BREAKING OF A LITHOTRITE IN THE BLADDER—LITHOTOMY—HOW THE SHAFT OF A LITHOTRITE SHOULD BE CONSTRUCTED.

By JACOB FRANK, M.D.,

CHICAGO, ILL.

Mr. L. G——, by means of a Thompson searcher, was found to have a calculus in the bladder. He was seventy years of age, always lived plainly, had suffered about seven years with the different symptoms of calculi. There was abundance of albumin in his urine. Microscopical examination revealed oxalic-acid crystals, pus-corpuscles, but no casts.

November 26, 1885, Drs. Parkes and Brown assisting, the patient was etherized, and a sound, size 19, American scale, was introduced into the bladder. This was soon withdrawn, and a Bigelow lithotrite (blades, size 19; shaft, size 11, American scale for measuring sounds) found its way readily into the bladder. The urine had been retained three hours previous to the operation, and now oozed out alongside of the lithotrite. Following Sir Henry Thompson's advice, the bladder was left empty. Without great difficulty, and in less than ten minutes, the calculus was in the grasp of the lithotrite. A turn of the screw insured a firm hold. The scale on lithotrite showed a measurement of two inches. I now locked the instrument and applied gentle force to the screw. Just as I had determined that the calculus was too hard and too large for the lithotrite, a snap was felt and heard. A few more turns of the screw proved that the instrument had broken. It was then withdrawn, with the exception of that portion of it which had broken off sharply and remained in the bladder. The lithotrite had been previously tested on a piece of brick the size of an ordinary hickory-nut to see how much force it would bear. The breaking of the instrument rendered an operation by lithotrity impossible. It was too late to resort to lithotomy on that day.

The condition of the patient was not adversely affected by the operation. That night and the day following he remarked that he felt as well as before the operation. Pulse and temperature were normal, and pain during micturition slight.

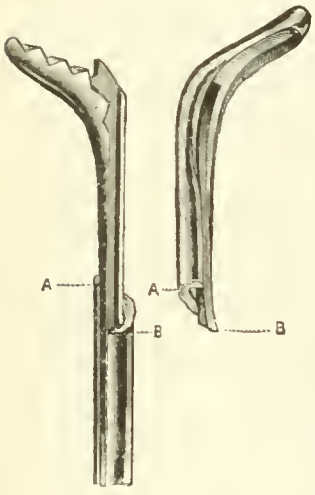
November 27th, twenty-four hours after the failure at lithotrity, the patient was again etherized and the lateral operation for lithotomy was performed; Drs. Miller, Parkes, Williams, and Brown assisted. During etherization the urine was unconsciously voided, and the bladder left empty. The calculus was first extracted in whole, and then the broken piece of lithotrite. The calculus is oxalate of lime and weighs two ounces.

After the bladder was emptied of its foreign bodies, the viscus was thoroughly washed with a two per cent. carbolic solution. As there was considerable venous oozing a shirted cannula was inserted and tamponed. This was removed in eigtheen hours, the bleeding having entirely ceased. The night following the operation the temperature rose to 101½° F., but before morning gradually fell to normal. It so remained until December 1st,

when the patient had a severe chill, his temperature rising to 102° F., and gradually subsiding during the day. It was normal the next morning and until December 16th, when patient again had a chill, and the temperature rose to 103° F. Next day pus appeared in the urine. January 22, 1886, there was great œdema of both feet. February 28th, three months after the second operation, the patient died with symptoms of uræmia. The autopsy showed pyelonephritis of the right kidney. The left one was almost twice its natural size, and filled with calculi. The bladder was empty, contracted, and the mucous membrane was thickened.

Now, I will not positively charge that the breaking of the lithotrite in any degree aggravated the condition of patient. Still, if many surgeons experienced a similar embarrassment with the instrument, lithotrity would soon become obsolete. Only an ordinary pressure was applied to the lithotrite, and the question naturally arises, Why did the instrument break?

As before stated, the instrument used was a Bigelow lithotrite—blades, size 19, and shaft, size 11, American scale for measuring sounds. Observe the great difference in the size of shaft and blades, a difference of eight sizes. There can be no adequate reason in favor of constructing the shaft so much smaller than the blades. But, on the other hand, had the size of the shaft more nearly approximated size of blades, the instrument would have been correspondingly stronger and safer.



Most lithotrites manufactured have the same fault as the one now under consideration. The following is a table of sizes of all lithotrites I have been able to measure:

Thompson's, manufactured by Tiemann & Co.: 1, Blades, 17—shaft, 10; 2, blades, 19—shaft, 13; 3, blades, 16—shaft, 12; 4, blades, 17—shaft, 13, American scale for measuring sounds.

Bigelow's, manufactured by Tieman & Co.: 5, Blades, 19—shaft, 10; 6, blades, 21—shaft, 14; 7, blades, 19—shaft, 11; 8, blades, 20—shaft, 13; 9, blades, 20—shaft, 15; 10, blades, 20—shaft, 16; 11, blades, 18—shaft, 11.

Bigelow's, manufactured by Codman & Shurtleff: 12, Blades, 18—shaft, 12; 13, blades, 21—shaft, 14.

Thompson's, manufactured by Shepard & Dudley: 14, Blades, 17—shaft, 10.

Manufactured by Marconi, of Vienna: 15, Blades, 17—shaft, 12.

From these tables it will be seen that lithotrites are not constructed according to an exact scale of sizes for the blades and shaft. But the latter are invariably much weaker, ranging from four to nine sizes smaller than the blades. Thompson's lithotrites appear to be a trifle better in this respect than Bigelow's.

My experience with the instrument as just related, together with an inspection of these tables, shows that the construction of lithotrites is not such as to give sufficient guarantee of security.

Now, why should not the size of shafts be made equal to that of blades, or, in case of the largest instruments, even two or three sizes smaller? If the blades pass through the urethra, the shaft will certainly follow with equal readiness. Thus constructed, lithotrites will best approximate absolute security in their use, and have at least the advantage of uniformity.

NOTE.—Dr. Charles T. Parkes, of Chicago, tells me that his lithotrite broke in the shaft while he was testing its strength on a piece of brick.

Clinical Department.

MICROSCOPIC EXAMINATION OF URINE.

ONE of our correspondents asks the following questions: 1. "Would it be practicable to have an article in THE MEDICAL RECORD upon the diagnosing of epithelia from the entire urinary tract?" Yes, it might be practicable, but at present we believe that it would be practically useless. Such an article might be "acceptable to the busy practitioner" who may not be an "expert microscopist," but the very fact that he is not an expert microscopist disqualifies him from appreciating such an article properly, even though the article could have a truthful basis, which we believe it would not have.

2. "What are the average sizes of the different casts?" Casts, so far as size is concerned, are of two varieties only, the large and the small, and this applies to all varieties. A small cast may be formed in a large tubule, the epithelia of which are intact. A large cast may be formed in a small tubule from which the epithelia have been removed.

The diameter of a tubule (not the normal lumen) varies in different portions. For example, the diameter of a loop-tubule is less than that of a convoluted one, or of a straight tubule in the cortical portion; while the diameter of a straight tube in the cortex is less than that of a tube in the pyramidal portion of the kidney.

By diameter is meant the *outside* measurement; for that of the *lumen*, when the epithelia are in position, varies so greatly that it cannot be estimated with a reasonable degree of accuracy.

The average diameter of the glomeruli is $\frac{1}{125}$ of an inch; of convoluted tubules, $\frac{1}{500}$ of an inch; of loop-tubules, $\frac{1}{1000}$ to $\frac{1}{2500}$ of an inch; of straight tubules in the cortex, $\frac{1}{625}$ of an inch; and then there is an increase in size until the papillary ducts are reached, the average size of which is about the same as that of the expanded portion at the other end. Other figures, doubtless, would be given by other writers.

In the midst of these possible sources of error, we should be inclined to doubt the accuracy of any observation which claimed to give the average diameter of casts.

3. "What does THE MEDICAL RECORD consider to be the average size of the epithelia from the convoluted tubules of the kidney, and to what extent do they vary in size?" Our correspondent goes on and says: "Should a person consult but one author the question is easily settled." In our opinion that is the way to settle it. For, as the correspondent continues, "Looking up authorities unfortunately only multiplies the difficulties."

Accuracy, in this instance, comes only from accepting the opinion of one observer, and then the average has considerable of the frailty of a single observation. The lack of uniformity in the "size" of the individual epithelial cells has made it necessary to make *outside* measurements for obtaining the diameters of the tubules in the normal kidney. For obvious reasons no average can be obtained of the size of the epithelial cells in morbid specimens.

Our correspondent suggests that the average red-blood corpuscle might be used as a standard of comparison for epithelia. We should question the utility of the proposed standard, for it would be, practically, guessing, after having seen the two objects.

4. "I would also ask, does THE MEDICAL RECORD consider it possible to *always* distinguish between the epithelia from the bladder and kidney?" The word "*always*" is very stringent. Taken literally, we should say that it is not always possible, etc. Taken with the latitude which one might be allowed after consulting "authorities," we are inclined to answer that such a consultation "unfortunately only multiplies the difficulties."

We are aware that some men claim to be able to differentiate all these cells, when seen in the urine under the microscope, with as much accuracy as when examined histologically in the tissues of the different parts of the genito-urinary tract. We incline to the opinion that the accuracy in one case is about the same as it is in the other, and that in neither instance can it be so done as to withstand the test of scientific criticism and completely satisfy the careful worker. Every practical microscopist knows that he encounters cells of doubtful origin in examining urine, and it is only the bigot who "*always*" knows whence they came. There are those who have claimed to be able to tell precisely from what portion of a uriniferous tubule a given cell came, but we doubt exceedingly if they have been able to convince their contemporaries that even all experts can acquire such extraordinary skill.

THE ANTISEPTIC TREATMENT OF CHRONIC LEG ULCERS.

Dr. George R. Fowler, of Brooklyn, sends the following communication: "I desire to call attention to a practical application of the antiseptic method in the treatment of intractable ulcers of the leg. I have employed it for some time past, to the exclusion of almost every other method, and can testify to the invariably rapid and extremely satisfactory results obtained. The method in question consists in first thoroughly disinfecting the leg, from the knee to the base of the toes, by means of a 1–4,000 solution of mercuric iodide, using the scrubbing-brush vigorously. The hard and elevated edge of the ulcer is now dissected away in such a manner as to leave a bevelled edge to the latter. If the base or bottom of the ulcer is occupied by a grayish, soft, and pultaceous, and but indifferently healthy, granulating material, it is best, in addition to the before-mentioned bevelling process, to curette by means of Volkmann's sharp spoon the whole of this away. A solution of the mercuric iodide is now to be again allowed to flow over the parts, in order to still further disinfect the same, after which a thick paste is made by mixing together oxide of zinc and hot water. The water is used hot only for the purpose of insuring that it is pure and untainted. This paste is to be spread, by means of a spatula, upon the ulcer and the surrounding parts. The surface of the ulcer is thoroughly covered with the paste, so that its cavity is entirely filled. A piece of oil-silk with a number of perforations in it for the purpose of facilitating drainage, is now placed over the site of the ulcer, and a cushion of paper-wool, or some other good absorbent material, is bandaged firmly over the parts by means of a gauze roller, and a starch or light plaster-of-Paris bandage applied over all. This dressing may be allowed to remain for a fortnight without being disturbed, providing no discharge makes its appearance in the meanwhile. Two or three such dressings are usually sufficient to cure the most obstinate ulcer.

"The antiseptic properties of oxide of zinc were first studied by Socin, of Basle, but very little attention seems to have been paid to the subject. I have had occasion to make use of the agent in many ways since it came to my notice, and can report, from a clinical standpoint at least, upon its antiseptic properties. It has served an excellent purpose in many ways other than the particular application to which attention is called in this brief note, particularly as a vaginal tampon, when incorporated in jute, after certain operations upon the uterus or cervix. Such tampons I have left *in situ* for more than fourteen days, at the end of which time they have been found to be as free from odor of decomposition as when introduced. The jute and oxide of zinc dressing makes a far more preferable dressing than the so-called "antiseptic marine lint," a preparation of jute and tar quite popular among gynecologists. This is far from constituting a reliable antiseptic dressing, and is open to the additional objection of being very dirty, speaking now in an æsthetic sense. The jute and zinc dressing is highly absorbent, and in fact is in every way a very desirable, cheap, and efficient dressing for the purposes mentioned in this note, as well as for many others which will suggest themselves to the mind of the practical surgeon. It sometimes happens that there is considerable flow of blood following the curetting operation, but there is no objection to this; in fact, according to Schede, of Hamburg, there is more rapid healing, providing a strict antisepsis is maintained, in the case of all wounds when a blood-clot is present under the dressing."

FRACTURE OF THE HARD PALATE IN A CHILD.

Dr. E. Harrison Griffin, of this city, reports the following interesting case: "Otto N——, male, aged two years and eight months, was referred to me by Dr. Holgate, on account of an injury to the throat. The history of the case is as follows: While playing with a piccolo, the child fell, and the sharp end being in his mouth, the instrument cut through the palate. The mother took him to a physician who recommended a gargle. This was used persistently for three days, but the child's throat did not improve. Whenever the patient attempted to eat or drink, some of the food found its way through the hole in the throat, and thence into the nose. I saw the case on the fourth day, and found upon examination that the lower portion of the hard palate was cut completely through, the injury extending downward and involving the soft palate. The injured portion of the hard palate, attached only by a slender piece of tissue to the soft palate, hung down, and rested upon the base of the tongue. The flap was congested and swollen. Upon a casual examination at the clinic, it seemed quite simple to pass a curved needle through the edges of the flap, and bring it into position; but when I saw the case at my office, I saw that the edge of the wound was so well up on the hard palate that an operation of this nature was impossible, unless holes were drilled through the fractured bone to accommodate the passage of the needle. If such an operation had been feasible, it would have been so in this case, as the child bore its suffering and allowed me to manipulate my instruments in its throat without any outburst of fear or terror. I had no occasion to use any anæsthetic. If the attempt had been made to drill or use much force in trying to sew the parts in position, the flap would have been torn from off its slender hold. On December 19th I sent the case to Dr. Perry, dentist, with instruction to make an obturator for the child's mouth, after the following manner: The plate was to be perforated for drainage, and one side was to go well down and against the soft palate, so that the flap could be held well into position. The plate was held in the mouth by cords attached to either molar tooth. On the following day the plate was in position and held the flap nicely in place. The child complained of a slight fever, possibly due to the wound being freshened; this was controlled with small doses of quinine and brandy. The patient was able to eat without any trouble. The case was seen every other day, and the throat was cleaned by spraying with Dobell's solution, without removing the plate. Two weeks after the plate was adjusted, I removed it and found the parts so completely healed that no mark of the injury could be seen. I think that this was the only rational way of treating this case. It could not have been brought in position by stitches, as the bony parts were involved, and violence would have torn off the flap. Had the gargle been persisted in, gangrene would have taken place and a permanent opening left through part of the hard and soft palate, and the voice would thus have been permanently impaired."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 2, 1887.

DISCOVERY OF THE BACILLUS OF SCARLET FEVER.

DRS. W. ALLAN JAMIESON and M. Alexander Edington, of Edinburgh, announce, in the last *British Medical Journal*, the discovery of a specific bacillus of scarlet fever. The micro-organism has been isolated, cultivated, and put through its paces generally, coming out, apparently, with a specific character.

The discovery may upset somewhat the recent conclusions of Klein as to the origin of scarlet fever from cows. Dr. Edington says that "it is pretty well proved that this bacillus scarlatinæ is the specific cause of scarlet fever, and probably the other organisms found in the blood during and at a later period than the bacillus are merely concomitants and pass into the blood only after the vitality of the system and tissues has been lowered by the entrance into them of this specific organism. But if one injects or otherwise inoculates a perfectly healthy animal with the diplococcus scarlatinæ sanguinis, one finds that it is able to live for some little time in the blood without, in the case of animals, giving rise to any marked symptoms. This being so, then it is quite logical to suppose that if such be carried in infecting desquamation along with the bacillus, a double infection may ensue. Whether in such a condition the action of the bacillus is modified by it cannot yet be definitely stated; but if we are to rely on what has been observed during the course of this investigation, then it might be stated that, in those cases where one finds an extremely vivid and general rash, there is usually present from the first the bacillus and diplococcus. Unfortunately, much cannot be said of those extremely rapid and excessively malignant cases, because, owing to various reasons, I was unable, with the exception of one case, to get the blood investigated, and in it there was present, in addition to the bacillus, the ascobacillus mentioned and described. One thing which is very certain is that this bacillus scarlatinæ is able to form spores in the blood of a living animal, thus differing from the bacillus anthracis, which only does so on the near approach of death.

"The rapidity of the growth of this organism—which is such that, if one inoculate a flask of broth, the diameter of which is two and one-half inches, and it be incubated, the pellicle will develop and cover it entirely over in the course of four hours—suggests an explanation of the very short period of incubation in scarlet fever."

Dr. Edington, who carried out the bacteriological part of the work, has failed to show that pure inoculations of cultivated bacilli cause scarlatina in man; also, that the supposed specific bacillus is not found in other diseases.

DOSIMETRIC MEDICINE.

READERS of current medical literature occasionally meet with some reference to dosimetry, dosimetric medicine, and the method of Professor Ad. Burqgraeve, of Ghent. To very few do these names convey any very definite ideas; but it is likely that the American profession will soon be enlightened through the agency of *The Dosimetric Medical Review*, a monthly journal recently started, and which is devoted to the propagation of dosimetry and the advertisement of the granular medicaments upon which the science is based.

After a careful perusal of a large amount of literary and scientific rubbish in the pages of the first issue of the *Review*, we manage to sift out the fact that dosimetry is the giving of medicines in the form of alkaloids or active principles. These are minutely divided, and used in varying doses as needed. It appears to be a claim of dosimetric medicine that it can "jugulate" inflammatory fevers. We observe a large number of "granules" advertised as the dosimetric medicaments of Professor Burqgraeve. We note, also, an article on the "Physiological Action of Strychnine," by the inventive and dosimetric professor himself. If it is a specimen of his literary skill, or of his ordinary methods of ratiocination, we are compelled to take a gloomy view of the distinguished dosimetrician's intellectual lucidity.

Dosimetric medicine seems to be only the giving of drugs in concentrated form and in very minute subdivision. This principle is well enough, but we fail to see why the pillules, granules, globules, and tablets now in the market will not answer all the purposes of a full-fledged dosimetrist.

THE CITY DOCTOR'S SUMMER PRACTICE.

WE have received two very earnest protests against the suggestions expressed in our recent editorial upon the above subject. Both communications are quite long, and we shall try to do them justice by presenting the views of the writers here. Of course, the tenor of our correspondents' arguments is to show that city physicians have no right to go into the country and draw away patients from the local practitioners. One writer affirms that the city doctor ought to earn his living in the fall, winter, and spring months. He says:

"If a physician desire to spend the summer in the country—a most commendable desire—he should do so as any other citizen. Who would expect the 'grocer, the baker, the candlestick-maker,' who spend their summers out of town, to peddle their wares to the country folk? The local dealers are expected to do this, and so with the physician; he has a prerogative which he exercises at *home*, and this he should so exercise that during the fall, winter, and spring months he *should* earn a sufficiency to enable him to live in the country *without* professional work; and if he do not do this he should stay at home during the summer and work, because he certainly *can* find enough to do to support him well, unless

he be a very young practitioner. In other words, no doctor has a right (an unwritten law) to leave his city practice to take care of itself, and his winter patients to go where they may, and seek 'support' in some watering-place—a procedure, to my mind, which argues very 'small business for the parties who do it.'"

Our correspondent waxes somewhat indignant as he progresses, and says:

"If I understand your remarks correctly, you would advise the physician to play the quack, the travelling one—the sneak—to leave his city practice and steal from the country, for what? 'To make all the twelve months of the year contribute to his support.' Surely showing a most greedy spirit, particularly when that support can be had from a city summer practice."

He concludes with the following summary of his views:

"1. Physicians who can make enough money during the winter months (I include fall and spring) for their support during the summer, should by all means go and have a good time, by letting practice alone.

"2. Physicians who cannot make such money should stay at home during summer and attend to their own and their more fortunate neighbor's practice.

"3. Country doctors should be allowed to reap the benefit from city patients during the summer."

We have not left much space for our other correspondent, but his arguments are in the same line. He adds, also, some remarks upon the abuses occurring in the summer practice of city doctors.

We are quite willing to open our columns to both city and country practitioners upon this subject. It is one that has been much discussed, and with little apparent practical result. We quite agree that there have been instances of very selfish interference on the part of city physicians during their summer work, and we certainly cannot urge too strongly the importance of respecting the rights and feelings of the country practitioner. To expect, however, a discontinuance of the practice of some physicians in cities transferring their work in the summer to various watering-places and other resorts in the country is absurd. During the season, for example, there are perhaps one hundred thousand transient visitors along the New Jersey shore, many of them being in localities where no country practitioner could be easily reached. There is no reason why an extra supply of physicians should not be on hand to attend to these crowds.

THE HEALTH-OFFICER AND THE IMPORTATION OF RAGS.

We have been decidedly inclined to favor the policy which the Health Officer of this port has adopted of enforcing the disinfection of imported rags. The charges of a corrupt association with a disinfection company have at least not been proved, and, at any rate, are entirely apart from the purely sanitary question of rag-disinfection. It has been abundantly demonstrated that rags are a source of disease, and it is the policy of most governments to look after their disinfection. The reported reappearance of cholera in France brings the matter again into prominence.

The most serious argument at present against attempts to disinfect rags is that there is as yet no known method which will surely effect the object without injuring the rags. This is especially the case with woollen rags, or rags of mixed cotton and wool.

OUR MEDICAL SOCIETY WORK.

The work of local societies for this season is about finished, and there is, we fancy, a sigh of relief from many a hard-worked physician who has had to add to his daily toil the task of evening sedentation at various medical meetings. There is a feeling just now that society work has been a little overdone. If we mistake not, the traces of previous drain on their resources is shown at some of the state and national associations now holding their sessions. In this city the doctor has had the exhaust machinery of some thirty medical societies applied to him monthly ever since last autumn, and it would be a little surprising not to find him more or less "pumped" at the present time.

The great and multifarious activity of our societies leads, perhaps, to some immaturity of work, and to the giving forth of a good deal that is trite or trivial. Yet, on the whole, such activity is good, and we trust it will be continued. Society meetings bring men together, disseminate knowledge more quickly, unify opinions, and promote immensely the solidarity of the profession. Doctors do not disagree on consultations, as was formerly the case, and medical practice is constantly becoming more rational and uniform, very largely through the instrumentality of medical societies.

THE REASONS WHY.

A recent issue of the *Tribune* contained this paragraph: "The Medical Record doesn't appear to like the publication in non-medical papers of remarkable cases of surgery. Doubtless the public would be interested to know why The Record is opposed to such a publication."

The above inquiry seems to be a candid one, yet "doubtless the public" would fail to appreciate many reasons which appeal cogently to medical men. Any great achievement in a branch of science is bound sooner or later to come to light; none more so than those which lessen the suffering or prolong the life of mankind. This achievement may be a brilliant surgical operation, involving new methods of procedure, or introducing new principles which shall become precedents for future guidance. So far as these relate to mankind at large, the latter have a right to learn thereof. The demand for news on the part of the public will speedily bring the salient features of the new knowledge to everyone's notice. This is the legitimate channel through which such knowledge should flow. The scientific journals first state it in technical and accurate knowledge. The "Medical-Notes" editor can make such extracts for his own use as his judgment may dictate. In so far, however, as the question at issue is one of pure medical science, capable of being understood only by medical men, and of interest only to them, it is not of any concern to the public whatever. If anyone evinces a desire for technical knowledge, let him consult a scientific journal. The rendering into popular vernacular of

scientific knowledge can be done only by a scientist. The numerous ludicrous blunders in the daily papers show the folly of any other course.

But it is not so much circumstances as the above that we declaim against. The papers are filled from time to time with accounts of very commonplace operations which are neither novel nor especially interesting. Certainly they are not to physicians, and only those who delight in "sickening details" can peruse them with any pleasure. The name of the operator is often given in full. Technical terms are used with sufficient accuracy to show that the article has at least passed under the eye of a medical man. If it is that of the surgeon himself, he is guilty of a breach of ethics in permitting the article thus to go before the public. If it is done without his knowledge, a protest on his part would insure its non-repetition. We do not know that any such protests have ever been made by several whose names might be mentioned.

The less the public know about details of surgical operations the better. Only the first-year medical student revels in knife, saw, and blood. The surgery of the present day certainly needs no screen. It stands in the front rank of progress; but from the very nature of its province it should not be made a topic of every-day newspaper badinage. Its own inherent dignity demands something better.

The foregoing views are not new to the profession. They are, however, our answer to the *Tribune's* suggestion.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The American Association for the Advancement of Science holds its thirty-sixth annual meeting in this city in August next. This is, we believe, the first time that this organization has ever met in New York City, and, as the great representative scientific body of our country, it deserves hearty support and welcome. It is unfortunate that so large a number of medical men will be away at this time, but we trust that all who can will aid the local committee or help, at least, to swell the audiences at the meetings. It would be most proper for all of our larger medical societies to take some active steps in co-operating with those who are to manage the affairs of this meeting. The County Medical Society has, we believe, done its share.

THE NEW BUILDING OF THE ACADEMY OF MEDICINE.

The New York Academy of Medicine is now the possessor of funds and property amounting to over one hundred and fifty thousand dollars, if we are correctly informed. With such a sum for a beginning its members ought no longer to tolerate the incompleteness of its present quarters. It is unfortunate that in a city of this size and wealth the medical profession should have for its headquarters a place so far below the present requirements. With money enough to start upon a new building there is no good reason for delay. With a site selected, the structure planned, and work begun, bequests and contributions will be sure to come. The givers of money like to know exactly where it is going, and to see some immediate tangible results from it. The Academy of Medicine cannot expect more money to be given them to be laid away at a low rate of interest until a "sufficient sum" is accumulated. The profession is anxious to have the new building begun, and it would be wise policy to accede to the wish.

News of the Week.

Nutritive Value of Mushrooms.—Dr. Stromer, of Vienna, concludes: 1. Mushrooms possess small nutritive value, their heavy charge of water reducing to very little their quantity of nutrient substances, and, above all, the albumen, which is difficult of digestion. 2. Dry mushrooms are not much better, because they absorb a great deal of water in cooking. 3. Mushrooms approximate in nutritive value to vegetables, particularly to cabbage, and, being cheap and easily procurable, deserve, *pro tanto*, the attention of the poor.—*Lancet.*

Tabular View of Zymotic Disease.—Dr. W. Squire has recently, as a result of mature experience and careful research, compiled a table relating to zymotic disease which is so excellent that we have thought fit to reproduce it:

Disease.	Period of incubation.	Interval of safety.	For rash or other sign.	Duration of infectiveness.
Small-pox ..	12 days	15 days	2–3 days	3–4 weeks.
Measles	8–12 "	18 "	3–4 "	3–4 "
Scarlet fever	2–5 "	8 "	2 "	6–8 "
Rubella	10–21 "	3 weeks	1–2 "	2 or 3 "
Chicken-pox	10–14 "	2½ "	1 "	2 "
Mumps	12–21 "	3 "	1–5 "	2 or 3 "
Whooping-cough	6–12 "	2 "	1–3 weeks	About 6 weeks.
Diphtheria ..	2–12 "	2 "	1–2 days,	6–8 weeks.
Enteric fever	5–20 "	4 "	10–12 "	4–8 "
Typhus fever	5–12 "	2 "	5 "	3 or 4 "
Cholera	2–5 "	1 "	Sudden	Uncertain.

We are glad to find him insisting upon a definite, fixed, and invariable incubation for small-pox; we should, however, prefer to say two to five days for the rash of measles to appear. He also seems to put the infective duration of diphtheria at too long a period; four to six weeks would be a more acurate one.—*Medical Press Circular.*

The New Method for the Treatment of Localized Tubercular Affections.—Considerable comment has been excited by the announcement of Dr. Kolischer, of Vienna, that he had discovered a new method for the treatment of localized tuberculosis. It has been suggested that it might be applied to the treatment of pulmonary disease. The correspondent of the *Medical Press* gives a full account of Kolischer's methods: The theory of his treatment is based on two principles, viz.: First, to supply the tubercular foci with a sufficient quantity of salts of lime, so as to effect recovery as in cases of calcification of tubercles in the lungs; secondly, to set up an acute irritation of the tubercular granulations, and thus produce a cicatricial shrinking of the nodules. In cases of tubercle which had not yet broken down, he availed himself of injection (into the parenchyma) of an acid solution of the biphosphate of lime, and when the growth was not undergoing a progressive caseous process, he obtained recovery in from four to eight weeks.

In cases of tubercular ulcerations and cold abscesses, he used gauze, which was saturated with the solution of lime prepared for this purpose, and he also obtained striking and rapid successful results. At the same time he stated that when the solution was not used with precaution, or when its constituents were not properly combined, the procedure under consideration might have bad consequences—such as had occurred in the beginning of his experiments. On this occasion he showed five patients who had been treated in this way with success, and among these, two cases of fungous granulations of the elbow-joint in children, with recovery, after a six weeks' course of treatment. In both cases the patients suffered from anchylosis, extensive swelling, with pain and fever. The joints were now quite normal after the treatment, and perfect mobility was obtained. The fever and the pain disappeared soon after the treatment was begun. He also showed a case of fungous granulation of the knee-joint with grave symptoms, such as anchylosis, lateral mobility, swelling, and pain, in a boy, aged four; recovery took place after five weeks. In a case of granulation of the tibio-tarsal joint, recovery also established after a short time. Professor Albert remarked concerning this communication that few facts had made such an impression upon him as the results of the experiments of Dr. Kolischer. He had at first sought to find out whether there was not some mistake in the results obtained; in the case of recovery of fungous granulation of the elbow-joint, he had thought that they might perhaps have had to deal with a peri-articular abscess with extra-capsular granulation, a process which he had occasionally observed; but the rapid recovery even in such a case would have been surprising. He said that this method of treatment was promising, and he emphatically recommended further researches by other surgeons. N Y Med. Record.

The Value of Subcutaneous Injections of Eucalyptol, in the treatment of phthisis, is now being discussed by the medical societies of Paris. The weight of evidence is that the treatment is not one of much value.

Madness in Royal Families.—King Otto, brother of the late King Ludwig, of Bavaria, has recently been pronounced insane. Princess Thyra, sister of the Princess of Wales, is confined in an asylum. One of the ladies of the royal house of Austria has recently become insane. *Per contra*, President Cleveland can stand a three weeks' course of black flies in the Adirondacks, and still preserve a condition of fine mental co-ordination.

Two New Medical Laws.—The bill to regulate the practice of medicine in Illinois has become a law, to go into effect on July 1, 1887. In its main features this new law resembles the old one, but the State Board of Health is given more definite powers. Itinerant venders of medicine are obliged to pay a license of $100 a month. This provision ought to be a powerful check on quacks. Governor Hill has signed the bill for regulating medical practice in New York. The law thus made is in effect a codification of previous statutes. It simplifies the law and makes its execution more feasible. It restricts the list of authorized practising physicians to those already regularly licensed and over twenty-one years of age. Hereafter those who shall be admitted to practice will be confined, first, to those who shall have been graduated from an incorporated medical school or college with the degree of Doctor of Medicine; second, to those who shall have received this degree from the Regents of the University of the State of New York; third, to graduates of incorporated medical institutions in other States and foreign countries which shall have been approved by the institutions in this State. The County Clerk of each county shall keep a registry book in which every physician must register according to a prescribed formula. No person convicted of committing a felony shall be allowed to practise. The penalty for violating the law is $50 fine for the first offence, and $100 fine or one hundred days imprisonment, or both, for each succeeding offence. The county medical societies are authorized to prosecute any offenders.

The Alumni Association Prize of the College of Physicians and Surgeons, New York City.—This prize of *five hundred dollars*, open for competition to the Alumni of the College, will be awarded to the best *medical essay* submitted to the Committee, upon any subject the writer may select. If no one of the essays be deemed sufficiently meritorious the prize is not awarded.

An essay, in order to be held worthy of the prize, must contain the results of original investigations or research made by the writer.

Competing essays must each be marked with a device or motto, and accompanied by a sealed envelope similarly marked, containing the name and address of the author.

Essays in competition for the prize to be awarded at Commencement, May, 1888, must be sent to a member of the Prize Committee, on or before April 1, 1888.

Andrew J. McCosh, M.D.,
William G. Thompson, M.D.,
M. Allen Starr, M.D.,
Committee.

Please mention The Medical Record.

New York Polyclinic.—Dr. J. W. Gleitzman has been appointed Professor of Laryngology and Rhinology, and Dr. O. D. Pomeroy Professor of Otology, in the New York Polyclinic.

Dr. N. Senn on Mr. Tait.—Dr. Senn writes to the *Journal of the American Medical Association:* "From what I gleaned from my observations in the practice of Mr. Tait, I have come to the following conclusions: 1. He is a skilful and dexterous operator. 2. He depends on a diagnosis by digital exploration in the majority of cases. 3. He removes the ovaries and tubes in cases for indications which few gynecologists would be willing to accept as justifiable for such a serious procedure. His wonderful success may be attributed to: 1, aseptic surgery; 2, small incisions; 3, no unnecessary exposure of peritoneal cavity; 4, perfect familiarity with pelvic and abdominal surgery as far as the mechanical performance of operations is concerned; 5, rapid operating; 6, careful personal supervision in the after-treatment. There can be no question that much of his success also depends on the fact that he performs his operations almost without assistance, and in this respect all laparotomists should

lose no time in imitating his example. With all his faults, Mr. Lawson Tait has done much toward the advancement of gynecology, and we may learn from him many a valuable lesson which will add to our success in practice." Dr. Senn seems to have been much disappointed because he could not get Mr. Tait to talk "shop" at his dinner-table.

Mr. Bryant's favorite antiseptic solution is a weak watery solution of iodine, which he prefers to any other antiseptic, and with which he has had most excellent results.

A Training-school for Male Nurses.—We stated recently, on the authority of the *Medical Register*, that there was no school for training male nurses as yet in working order in this city. We learn, however, from Superintendent Dr. James F. Ferguson that the Commissioners of Charities and Correction have recently organized the "Charity Hospital Training-school for Male Nurses." Applicants must be between the ages of twenty and thirty. The school is under the direction of a Board of Managers, of whom Dr. Ferguson is Chairman.

The Murder of a Physician.—Dr. Edward H. Duggan, of Brooklyn, was shot and killed by a man named Weidler, on June 24th. Dr. Duggan was a physician in large practice, and a graduate of Long Island College Hospital, in 1861. The motive for the murder is unknown.

Some of our Southern State Medical Societies have had to engage in the unpleasant task of defending assaults upon the character of its members. Dr. F. Daniel received a thorough exculpation at the hands of the Texas State Medical Society from charges made against him by one of the members. We observe that at the meeting of the Kentucky State Medical Society, Dr. Dudley S. Reynolds was the victim of certain aspersions, which the State Society "repelled" in formal resolution. Both Dr. Daniel and Dr. Reynolds are medical editors, which is *prima facie* evidence that they are good and able men. But the life of the medical editor is beset with snares. We congratulate our contemporaries on having escaped this time at least.

Investigating a Hospital.—Charges were recently made that there were a number of abuses in the conduct of Gouverneur Hospital of this city. More particularly one of the house physicians was charged with intoxication and making unseemly noises in his room. Investigation showed that while there had been, a good while ago, some irregularities among the employees, these had been corrected, and that the present charges were the work of discharged employees.

Billroth on Medical Progress in France.—Our esteemed French exchanges are much exercised over the recent statement by Billroth that Pasteur's anti-rabic inoculations were useless, and the supplementary remark, that in the past twenty years France had not only made little progress in medical and surgical science, but had hobbled painfully in the wake of the colossal advances of German and English science. The sting of this remark is in its truth. France is behind, is almost provincial in its relation with the state of science in other countries. It is due not to French dulness or idleness, but to its self-sufficiency, which has led its scientific men to grow up in the belief that there is little of importance outside of France. A change is taking place now, however.

Yellow Fever still exists at Key West, one or two new cases being reported daily.

The State Medical Society of West Virginia will hold its Twentieth Annual Meeting at Greenbrier, White Sulphur Springs, W. Va., July 13 to 15, 1887, inclusive.

Post-Graduate Medical School.—Dr. George B. Fowler has been elected by the Board of Directors Professor of Clinical Medicine and Medical Chemistry.

The Ohio State Medical Society.—Through an error last week, we stated that the Ohio State Medical Society met in Cincinnati. It should have been in Toledo. Hon. Samuel F. Forbes, late Mayor of that city, was elected President unanimously. Columbus was selected as the place, and the first Tuesday in June, 1888, as the time for holding the next annual meeting.

There is Something in the atmosphere of St. Louis which gently turns the thoughts of medical editors to puns. This *paranomasia endemica* was observable several years ago in the *Alienist and Neurologist*. It has deeply affected the *Weekly Medical Review*, and we observe evidences of a pun-wave in a recent issue of the *St. Louis Medical and Surgical Journal*, which has the following: "Buttermilk for Babies is the title of a paper by Dr. Ottersen in the *Massachusetts Medical Journal*. If the baby has the right kind of a mother, it will not want any but her milk."

The Action of Strophanthus Hispidus.—The therapeutical and physiological effects of strophanthus were brought before the notice of the K. K. Gesellschaft der Aerzte of Vienna, on April 29th, by Professor Drasche. He reports that in his hands, and in those of Professor Bamberger, it had fully satisfied the expectations raised regarding it, and that it was already finding its way among the private practitioners of the Austrian capital. He had not hitherto used the full dose recommended by Fraser, in fact only the half of it, but in future he would give the quantity prescribed by its introducer. The pulse-rate invariably fell after its administration—sometimes in a few minutes, sometimes in the course of half an hour—and continued slower for several hours. In a typhoid case, the pulse was kept at 52 for fully eight days. One patient complained of muscular weakness after a dose, so that she could scarcely sit up. In the case of a nervous patient, with a pulse of 140 to 150, ten minims three times a day reduced the rate to 20 beats. This action was still constant, and took place almost immediately. In a case of Basedow's (Graves') disease with tumultuous cardiac action, twenty drops of the tincture effected improvement, and the arythmia present was also somewhat improved. He had treated thirty cases of actual disease of the heart with the drug, and he must confess that he was quite contented with its action. Exaggerated cardiac action was reduced more quickly and surely than by either digitalis or adonis.—*Medical Press.*

Reports of Societies.

NEW JERSEY MEDICAL SOCIETY.

One Hundred and Twenty-first Annual Meeting, held at Beach Haven, N. J., June 14 and 15, 1887.

TUESDAY, JUNE 14TH—FIRST DAY—AFTERNOON SESSION.

THE PRESIDENT, DR. C. J. KIPP, called the meeting to order, immediately after which prayer was offered by RIGHT REV. BISHOP SCARBOROUGH.

After the roll-call the Committee of Arrangements stated that the members of the Society were indebted to the officials of the Pennsylvania Railroad Co. for their kindness in granting a special train from Jersey City to Beach Haven, and for the efficient manner in which they had it advertised; to the officers of the Tuckerton Railroad Co. for a similar consideration and favor. A complimentary banquet was tendered to the Society and its visitors by Charles T. Parry, Esq., of the Baldwin Locomotive Works, of Philadelphia, and served by Mr. Joseph Page, the proprietor of the hotel, at 10 P.M., June 14th.

The Beach Haven Yacht Club tendered the delegates and visitors a complimentary sail on the bay at nine o'clock Wednesday morning.

THE ADDRESS OF WELCOME

was given by DR. T. T. PRICE, Chairman of the Committee of Arrangements. After the reading of this paper, which was expressive of a hearty and generous welcome, DR. WILLIAM PIERSON, of Orange, N. J., read the minutes of the last annual meeting.

CORRESPONDING MEMBERS.

It was then moved by Dr. Price, that Drs. John B. Roberts, Frank Fisher, Carl Seiler, Samuel Ashhurst, Dr. Woods, Gabriel Grant, Professor Leidy, and Bishop Scarborough, be invited to sit with the Society as corresponding members. Carried.

TOPICS FOR DISCUSSION AT NEXT ANNUAL MEETING.

The Committee on Business, in their report, suggested that the topics for extemporaneous discussion at the next annual meeting shall be:

1. The relation of laundry and dish water to the spread of disease.
2. Local anæsthesia in minor surgery.
3. The treatment of phthisis by gaseous enemata.
4. What treatment will most effectually and promptly curtail the course of acute rheumatism.

It was determined by vote that the first, third, and fourth topics should at the next annual meeting be the subjects for discussion.

DR. JOSEPH W. STICKLER WINS THE FELLOWS' PRIZE.

The Committee on Fellows' Prize Essay then made their report, and recommended that the sum of $100 be given to Dr. Joseph W. Stickler, of Orange, N. J., for his essay, entitled "The Climatology and Diseases of Essex County, N. J." Carried.

DR. PRICE moved that the Society take up that portion of the business of the evening after the report of the Standing Committee. Carried.

TREASURER'S REPORT.

DR. W. W. L. PHILLIPS, of Trenton, Treasurer, then reported that the total receipts from the societies amounted to $951 50
Balance from last year 760 77

Total balance $1,712 27
Total disbursements 1,227 25

Balance on hand $485 02
Assets—U. S. bonds, four per cent 2,550 00
Newark Savings Bank 45 69

$2,595 69

THE CORRESPONDING SECRETARY'S REPORT

was read by DR. WILLIAM PIERSON, as Dr. William Elmer was unavoidably absent. The report showed that exchanges had been received from the following States: Maine, New Hampshire, Vermont, Massachusetts, Connecticut, New York, Pennsylvania, Maryland, West Virginia, North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, Texas, Tennessee, Ohio, Illinois, Michigan, Wisconsin, Minnesota, Missouri, Colorado, and Oregon; also from the College of Physicians and Surgeons, Philadelphia. The Committee also received from the *Journal of the American Medical Association* a statement to the effect that they propose to publish in the *Journal* a register of the state and county medical societies of the United States, commencing January 1, 1887. "As it will entail considerable expense, we are compelled to make a nominal charge, namely: $6 per annum, where it makes a single line; $10 for two lines, and $12 for three lines, which will include a copy of the *Journal* sent free every week."

THE PRESIDENT reported the following

COMMITTEES.

On Honorary Membership: Drs. Baldwin, Pennington, and Oakley.

On Business: Drs. Baldwin, Joseph Osborne, T. R. Parrish, W. A. Elmer, Samuel Green.

On Treasurer's Report: Drs. Chambers, Bodine, and Treganowan.

DR. OAKLEY moved the preparation of an obituary of Dr. Ryerson. The committee appointed for this purpose by the President consisted of Drs. Hunt, Pennington, and Wickes.

The Committee on Honorary Membership reported that they had received, through Dr. Genet Taylor, the names of Dr. D. Hayes Agnew, and Dr. Joseph Leidy, of Philadelphia, as proper persons upon whom to confer this title. These gentlemen were unanimously elected to honorary membership.

EVENING SESSION.

The first order of business was the reading of the

ANNUAL ADDRESS,

by the President, DR. CHARLES J KIPP, of Newark, N. J. His subject was

THE TREATMENT OF PURULENT INFLAMMATION OF THE MIDDLE EAR AND ITS CONSEQUENCES.

He said that in the treatment of the acute form of this disease he had pursued essentially the same line of treatment, whether the disease occurred independently of, or in connection with, some general disease, such as the exanthemata and typhoid fever. Rest of body and mind is now held by all authors to be an essential part of the treatment, and Dr. Kipp thought rightly so. At the same time he had treated hundreds of cases of this disease in the out-door department of the hospital, and, as a rule, recovery had been as rapid and complete in these cases as in those which had been kept in bed while the disease was at its height. For the relief of the violent pain in the ear and the head the doctor had found that, so long as the purulent secretion remained pent up in the tympanic cavity, the most satisfactory treatment was a free incision of the membrana tympani. He had performed this little operation many hundred times, and, although it has now and then failed to relieve the pain at once, he had never had occasion to regret making it in such cases. The operation is, as a rule, not very painful.

Cocaine, so far as his experience is concerned, is of but little value as an anæsthetic of the drum-membrane. The incision had generally been made with a broad lance-shaped needle. In most cases he considered it advisable to assist in the removal of the secretion from the tympanic cavity by gently inflating the middle ear

through the Eustachian catheter, or by Politzer's method immediately after the paracentesis. The recurrence of the pain is sometimes due to the complete or partial closure of the perforation and the consequent reaccumulation of the exudation in the tympanic cavity. In such cases he either reopened or enlarged the original perforation, or if this was situated in the upper part of the drum-membrane, he made a new incision in the lower posterior quadrant in order to secure better drainage.

Occasionally he had found it necessary to repeat this operation several times in the course of a few weeks. In other cases the pain was found to be due to the formation of furuncles, or to a diffused inflammation of the walls of the canal, or to periostitis of the mastoid process. Dr. Kipp is positive in the belief that the free use of the knife in cases of diffused inflammation of the walls of the canal prevents any subsequent phlegmonous periostitis of the canal. Periostitis of the mastoid process, when it does not subside in a few days under leeches and ice, the doctor treats with the knife, making an incision through the soft parts down to the bone. The various astringents used by Dr. Kipp in the treatment of cases in which the otorrhœa does not speedily cease under simple syringing and inflation, although the opening in the drum-membrane is sufficiently large and favorably situated for thorough drainage, are the acetate of lead, the sulphate of zinc, and the acetate of aluminium.

With regard to the treatment of caries and necrosis of other parts of the temporal bone than the mastoid process, experience has led the doctor to do little besides thorough cleansing of the middle ear and the extraction of the sequestra after they have found their way into the external canal.

Dr. Parvin, of Philadelphia, and Dr. Weir, of New York, were invited to take seats on the platform.

Dr. Oakley moved that the prize essay be published. Carried.

All guests who had arrived since the afternoon session were invited to sit with the Society.

Dr. T. I. Smith, Chairman of the Standing Committee, submitted his report. It was received and referred to the Committee on Publication.

The subject for discussion—

WHAT IS THE PERSONAL EXPERIENCE IN THE USE OF ANTIPYRIN?

Does it permanently reduce the temperature of the body or modify the course of disease? was introduced by Dr. H. R. Baldwin, who said that ephemeral fever is reduced by ten-grain doses repeated two or three times; when given in this manner it produces diaphoresis, which sometimes is very free. In typhoid fever it does not permanently reduce the temperature, but does frequently weaken the action of the already exhausted heart. For this reason he was very careful in its use in cases of typhoid fever and pneumonia. Drs. Helfer and T. N. Quimby endorsed the views expressed by Dr. Baldwin.

THE REPORT OF THE COMMITTEE ON ETHICS.

The Committee on Ethics in their report offered the following resolutions, namely: 1. That in view of the non-concurrence of other State societies in the recommendation of this Society on the subject of preliminary education, it is not expedient that further action be taken by this Society in reference thereto. 2. In reference to the request that this Society advertise its officers in the register of the *American Medical Association Journal*, we deem it inexpedient at present. 3. In reference to a subscription by this Society toward defraying the expenses of the Ninth International Medical Congress, your committee recommend such subscription as worthy of favorable consideration, but leave the amount to be fixed by the Society.

Adopted.

After a short discussion upon the last recommendation, the Society adjourned at 10.05 P.M. to attend the complimentary banquet.

WEDNESDAY, JUNE 15TH—SECOND DAY—MORNING SESSION.

OFFICERS FOR THE ENSUING YEAR.

The Nominating Committee made the following report:

President—Dr. J. D. Ward.

First Vice-President—Dr. H. J. Taylor.

Second Vice-President—Dr. B. A. Watson.

Third Vice-President—Dr. J. S. Green.

Corresponding Secretary—Dr. Wm. Elmer.

Recording Secretary—Dr. Wm. Pierson.

Treasurer—Dr. W. W. L. Phillips.

Standing Committee—Drs. I. J. Smith, E. J. Marsh, and D. C. English.

Delegates to American Medical Association—Drs. Godfrey, Quimby, W. H. O. Taylor, Coleman Leaming, W. H. Elmer, D. M. Skinner, S. T. Stiger, W. S. Crevelling, J. T. Wrightson, Dr. Risk, J. H. Balleny, G. B. Probosco, T. T. Welch, J. Wolverton, W. B. Watson, and Dr. Price.

Delegates to State Societies—Connecticut: Drs. B. Craig, Buckingham, and S. H. Hunt. Massachusetts: Drs. Wm. S. Laylor, S. A. Harris, and G. B. Brumley. Pennsylvania: Drs. Ridge, Weeks, and Arrowsmith. Rhode Island: Drs. H. M. Weeks, G. W. Terry, and Alonzo Pettit. Delaware: Drs. J. T. Wrightson, Geo. T. Welch, and J. C. Herrick. New York: Drs. T. R. Varick, D. A. Currie, and J. D. Osborne. Kentucky: Drs. Pomyea, Turnure, and Treganowen.

Committee of Arrangements—Dr. J. S. Cook, Hackettstown; Dr. W. H. Risk, Summit; Dr. Miller, Boonton; Dr. F. Bookeley, Dr. B. A. Watson.

Place of Meeting in 1888—Lake Hopatcong, N. J.

Business Committee—Drs. H. R. Baldwin, T. R. Varick, J. D. Osborne, W. H. Elmer, and W. Selover.

MONEY FOR THE INTERNATIONAL CONGRESS.

The recommendation of the Committee on Ethics, that the New Jersey State Medical Society subscribe toward defraying the expenses of the Ninth International Medical Congress, was annulled after a very spirited discussion, and the following resolution (by Dr. D. C. English) adopted, namely: That this Society, doubting the propriety of voting the funds of the Society toward defraying the expenses of the Ninth International Congress, commends the appeal to the members of this Society, and hereby appoints Dr. B. A. Watson a committee to receive contributions and forward them to Dr. Dunglison, the treasurer of the Congress. Carried.

The Committee on the Treasurer's Accounts made their report through Dr. T. R. Chambers.

Dr. B. A. Watson, of Jersey City, read a very interesting paper on

RATIONAL MEDICINE VERSUS EMPIRICISM.

He said the proper consideration of our subject demands a careful investigation of the fundamental principles involved in the practice of each. Rational medicine takes cognizance of the nature of disease, including its etiology, semiology, pathology, etc., and likewise the physiological action of remedies, while we seek to counteract the morbid processes of the one by the influence of the other. Furthermore, it is equally important that the practitioner of rational medicine should thoroughly understand the physiological and chemical laws which pertain to the performance of the various functions of the several organs of living beings, in order that he may intelligently regulate the hygienic and sanitary conditions of his patients. In addition to all this, it is highly important that every disciple of the great Hippocrates should possess a *practical* knowledge of the sciences which are allied to those of medicine, that he may thus be strengthened and the better prepared for the performance of the high duties of his profession. The physician must possess that faculty which enables him to reason accurately—to draw his scientific conclusions with unerring cer-

tainty. He must be able to analyze every symptom of disease and every logical induction, giving to each its proper place in the mental picture that forms the basis on which stands every accurate diagnosis. It is thus apparent that the rational practice of medicine is based on scientific knowledge and scientific reasoning. What is empiricism as differentiated from rational medicine?

History informs us that a sect of physicians, formerly designated by the name of empirics, originated with Phillinus, a pupil of Herophilus, and with Serapion, the successor of Phillinus, and that they were the advocates of the sceptical philosophy of Pyrrho. These ancient empirics principally occupied themselves with the discovery of the medicinal properties of drugs, while they neglected almost entirely the study of anatomy, pathology, physiology, chemistry, and the other sciences allied to medicine. Modern empiricism is embodied in the theory and practice of Hahnemann's followers, and how senseless seems the twaddle of the founder of homœopathy when viewed by the light of modern science!

Dr. D. Benjamin, of Camden, was expected to read an essay on "The Present Position of Antiseptic Practice," but he was detained by sickness. His essay was referred to the Committee on Publication and will appear in the "Transactions" of the Society.

TO REGULATE THE PRACTICE OF DISSECTIONS THROUGHOUT THE STATE.

Dr. J. P. Davis presented the following preamble and resolution, namely:

Whereas, While the laws of the State of New Jersey do not directly prohibit dissections of the human body, they do, by various provisions regulating burials and the transportation of dead bodies into and through the State, practically prohibit such dissections; and whereas such anomaly of law tends to retard the progress of medical science within the State, if not to a disregard of existing laws; therefore,

Resolved, That a committee be appointed to secure such modification of the State laws as may be necessary to permit and regulate the practice of dissections within the State. Carried. A committee, consisting of Drs. Davis, B. A. Watson, and E. M. Hunt, were appointed to make all necessary regulation in the matter.

Dr. Edward J. Ill was appointed essayist for next year.

Adjourned.

Afternoon Office-hours for Physicians.—A correspondent writes: "May I make a suggestion, or rather ask your opinion, about the office-hours of physicians? It matters little, perhaps, whether bedridden patients receive calls from their physicians in the morning or in the afternoon. But it seems to me that most walking patients could call on their physicians more conveniently after than before the usual midday meal. Thus, the streets and retail stores are more thronged by women in the afternoon than in the morning. The inference is that the afternoon is the time when they can most conveniently be absent from home Now, women are food and drink to physicians. Again, the hour after luncheon, or an hour toward evening, is more likely to be a leisure time with a business man than any hour of the morning. And feeble invalids, of both sexes, who generally feel out-of-sorts in the morning, often tone up sufficiently to walk out in the afternoon. My proposition is, that any physician having a considerable office-practice might add to it, and please all his patients, by arranging his affairs in such a manner as to make his office-hours from 2 to 6 P.M. Another proposition is, that a physician, having announced certain office-hours, is under moral obligation to be in his office, ready for business, during the whole of those hours, whether anyone is waiting to see him or not; and that the fact of his having lost a night's rest does not relieve him from this obligation."

ONTARIO MEDICAL ASSOCIATION.

Seventh Annual Meeting, held in Toronto, June 8 and 9, 1887.

Wednesday, June 8th—First Day—Morning Session.

The Seventh Annual Meeting of the Ontario Medical Association was held in the auditorium of the Normal School Buildings, Toronto, and was presided over by Dr. J. H. Richardson, of Toronto, the President.

The number present on the first day was over two hundred, and included medical men from every part of the Province of Ontario.

Dr. Duncan submitted the report of the Committee of Arrangements, and explained what steps had been taken to receive visitors; also the order of business. The report was adopted.

On motion of Dr. Bruce Smith, of Seaforth, and seconded by Dr. Rosebrugh, of Hamilton, a telegram of congratulation was sent to the American Medical Association, then holding their Thirty-eighth Annual Meeting in Chicago.

CONGRATULATIONS TO THE QUEEN.

On motion of Dr. J. E. White, seconded by Dr. Thorburn, of Toronto, the following jubilee cablegram was sent to Her Majesty the Queen:

"The President and members of the Ontario Medical Association, representing the medical profession of Ontario, at their annual meeting, desire to express to Her Most Gracious Majesty, Queen Victoria, their sincere pleasure upon the completion of the fiftieth year of her reign, their steadfast loyalty to her throne and government, and their lively hopes that a beneficent Providence, which has directed and comforted her through her past, may grant health, comfort, and happiness for many long years to come."

A member: I move that the word "Canada" be inserted after "Ontario," so that the English officials may not think Ontario is a small village in the heart of Asia (laughter, and "agreed"). The motion was then carried by a standing vote, all present joining in singing the national anthem.

MEDICAL DEFENCE FUND.

The question of forming a medical defence fund came up from the minutes of last year's meeting, and Dr. Henderson, of Kingston, moved that the following committee be appointed to consider and bring the subject before the meeting next day: Drs. Harrison, of Selkirk; Thorburn, of Toronto; Moore, of Brockville; Taylor, of Goderich; and the mover.

In supporting the motion, Dr. Henderson said that there was no more crying need on the part of the medical profession than the taking of steps to protect themselves from unjust and unfair accusations. The case which called his attention specially to the subject was one which had occurred in Eastern Ontario, and in which a medical practitioner had been prosecuted three years after he had ceased to attend the patient, who had emerged from sickness—an attack of periostitis—with a fair recovery, in the opinion of eight medical men who had been afterward consulted. The judge before whom the case was tried charged strongly in favor of the defendant, but the jury failed to agree, and the case was liable to be opened at any time, while already $1,000 had been spent by the defendant, and his practice greatly injured. If the Association would form a department or a fund to defend in such cases, it would be a powerful means of good; this Association would attract even more members than at present, and it would be a means of greater usefulness in more closely uniting the members of the profession in the Province. The motion was heartily agreed to.

A PROVINCIAL MEDICAL LIBRARY.

It was moved by Dr. McPhedran, and seconded by Dr. N. A. Powell, that Drs. Mullin, of Hamilton; Ar-

nott, of London; and Henderson, of Kingston, be appointed a committee from this Association to act with a committee from the Toronto Medical Society in the formation of a Provincial Medical Library.

INTRODUCING VISITORS.

THE PRESIDENT introduced to the Association and welcomed to the platform the following visitors, who received a most cordial reception: Drs. Gerster, G. H. Fox, Porter, and Satterthwaite, of New York; Dr. J. H. Packard, of Philadelphia; Drs. Cronyn and Hubbell, of Buffalo, N. Y., the latter representing the New York State Medical Association; Drs. Manton and Duffield, of Detroit, the latter being a delegate from the State Medical Society of Michigan; and Drs. Stewart and Cameron, of Montreal.

DR. PACKARD (on being introduced) remarked that there were fierce but interesting discussions at the present time on the subject of reciprocity between Canada and the United States, and also on the fisheries question. In the fisheries question it seemed to him there was nothing in it but a cod, not worth eating, anyway (laughter). He was in favor of reciprocity—certainly as far as the medical profession was concerned; and he hoped the *entente cordiale* now existing in that respect between the two countries would never be broken (cheers).

DR. CRONYN remarked that his friend Dr. Packard omitted the very point that was required. He should have advised the medical gentlemen before him to go to the United States and take possession there, as he (the speaker) had done many years ago (cheers).

The other visitors each made a few pleasing remarks, expressing their pleasure at being present.

PRESIDENT'S ANNUAL ADDRESS.

The President, DR. J. H. RICHARDSON, of Toronto, then delivered his annual address. He said it was difficult for one in his position to choose a subject to discourse upon in the presence of such an audience as that before him. It was not desirable for one man to set himself up as an authority or to deal with any one topic. He therefore chose to make a brief reference to some of the improvements, during his experience of forty years, in the general methods of medical treatment. Had he chosen anatomy he might, he said, feel more at home in his subject; but it might not be out of place to take a retrospective view of general medical treatment. He had been a close observer of the nature of disease, and had watched the changes which had taken place in the views regarding the nature of disease, and consequently in the modes of treatment. Forty years ago inflammation was considered to be at the root of almost all diseases. The most incongruous diseases were ranked under the head of "inflammatory diseases." As a remedy, bleeding was practised very largely until 1853. In Toronto it was practised for scarlet fever until 1860, frequently with the most disastrous results. He would refer more especially to two diseases, in regard to the treatment of which great improvement had taken place within the last quarter of a century, viz., splenic fever and hydrophobia.

Dr. Budd, of Bristol, seemed to have had the high distinction of being the first British physician to foresee the importance of the agency of minute organisms in the propagation of disease. Dr. Budd seemed to have been led to this prevision by the fact of the invariable reproduction of every specific disease. Splenic fever was a terrible scourge in Europe, how malignant, might be gathered from one paragraph from Touissant: "The period of its incubation is very short. An ox which has been at work may return to its stall apparently healthy. He eats as usual; then he lies down on his side and breathes heavily, while the eyes are still clear. Suddenly his head droops; his body grows cold; at the end of an hour the eyes become glazed, the animal struggles to get up, and falls dead—the struggle only lasting for an hour and a half."

Davaine, as early as 1850, discovered the presence of minute rods in the blood of animals which died from splenic fever; but it was not till 1863, after Pasteur's researches into the part played by microbes in fermentation, that he suspected their real agency in the production of disease. Pasteur's experiments are well known; his last experiment was made at the invitation of the President of the Society of Agriculture, and was watched by Pasteur's colleagues, who feared he had been too rash. A flock of sheep was divided into two groups, being all vaccinated with attenuated virus, while those of the other group were left unvaccinated. A number of cows were also subjected to a precisely similar treatment. Fourteen days afterward all the sheep, vaccinated and unvaccinated, were inoculated with a very violent virus, and three days subsequently more than two hundred persons assembled to witness the result. Twenty-one of the twenty-five unvaccinated sheep were already dead, and the remaining four were dying. The twenty-five vaccinated sheep were in full health. A similar result occurred among the cattle. The breeders of cattle at once overwhelmed Pasteur with applications for vaccine, and by the end of 1883 nearly five hundred thousand had been protected. Pasteur's crowning triumph was achieved over that dread disease, hydrophobia, which had hitherto baffled medical skill. After repeated experiments he determined: "1. That the virus attained its most intense virulence in the marrows of the infected animals. 2. That the virus of a mad dog, inoculated by trephining under the *dura mater* of a rabbit, always communicated rabies to the animal after a period of incubation of about fifteen days. 3. That successive inoculations with virus so obtained show a marked tendency to a diminution of the period of incubation down to seven days, when the virus seems to have attained its greatest intensity. 4. That portions of these marrows exposed to dry, uncontaminated air gradually lose their virulence, until at last it dies out."

Vaccine virus was not an invariable protection against small-pox; nor was small-pox itself a protection against subsequent attacks, and more must not be demanded for vaccination against hydrophobia than from vaccination for small-pox. Instead of cavil and doubt, we ought to lay hold with gratitude and confidence on the grand fact which had been established conclusively by direct experiment; viz., that some of the most deadly diseases which affect human and brute creatures are the result of the introduction of micro-organisms into the animal system; that they have been isolated and reproduced, generation after generation, by the most guarded, precise, and definite methods of the laboratory, and that they can be so modified in their strength as to be safely introduced into healthy animals and so protect them from the deadly effects produced by the unmodified poison.

In view of the facts of the discoveries of recent years they might surely "thank God and take courage" for the future.

The difficulties before them were great. The life-history of each class of these minute beings was so different, and the conditions under which they must be investigated were difficult, but there was no royal road to knowledge, and perseverance and research were certainly necessary. Yet they were on the road, and it only needed courage, faith, and constant advance to open up newer, larger, and brighter vistas of truth (cheers).

PAPERS READ.

DR. FENWICK, of Kingston, read a paper on "Lacerations of the Cervix Uteri."

Several questions on points touched on in the paper were put by members, and answered by Dr. Fenwick.

A valuable paper was read by DR. GROVES, of Fergus, on "Prostatotomy," which was well received, and spoken to by several members.

DR. FERGUSON, of Toronto, followed with a paper on "Arsenical Neuritis," causing an interesting discussion,

in which Drs. Covernton, Thorburn, Stewart, Teskey, Sheard, and others took part.

A discussion on "Medicine," subject, "Phosphaturia," was opened by Dr. Arnott, of London, with a sententious and able paper. He was assisted in the exposition of his subject by Drs. Bruce Smith, of Seaforth; McDonell, of Orillia; and Thorburn, of Toronto. Drs. Brown, of Galt; Powell, of Ottawa; and Strange and Ferguson, of Toronto, took part in the discussion which followed, and the paper was considered of a valuable and suggestive character.

VARIOUS METHODS OF TREATING SKIN DISEASES.

The next paper was one by Dr. G. H. Fox, of New York, on the various methods of treating skin-diseases, with special reference to the use of chirurgical instruments. Dr. Fox produced photographs of diseases before treatment, and of the skin in its restored condition, and exhibited some of the instruments used for punctating and cutting. He also showed two patients he had operated on that day, and whose disfigured faces, he said, his method would by an earlier application have perfectly cured. Drs. Graham, Oldright, and Holmes took part in the discussion which followed.

A paper by Dr. Murray, of Thorndale, on a "Case of Laceration of the Femoral Artery," concluded the session.

All the papers drew largely on the writer's experience in his ordinary practice or actual experiment, and in the discussion difficulties in the way of operating or prescribing remedies were considered, resulting in a great deal of practical information being elicited which must be of benefit to the members.

All the authors of the papers read were thanked by the President on behalf of the Association.

Evening Session

EXTRA-UTERINE PREGNANCY.

The Association resumed in the evening at eight o'clock.

Dr. Taylor, of Goderich, read a paper giving the history of a case of extra-uterine pregnancy. The patient recovered.

Dr. James Ross gave the history of two similar cases, the only two which he had observed out of several thousand cases of pregnancy which had come under his notice. In the last case abdominal section had been performed on the patient in St. John's Hospital, Toronto, by his son, he and other surgeons assisting. The patient is recovering.

Dr. A. G. Gerster, of New York, was cordially received. He read a paper on the

ANTISEPTIC PRINCIPLE, AS APPLIED TO THE TREATMENT OF PRIMARY INDURATION, AND THE INITIAL SORE OF SYPHILIS.

The paper provoked a good deal of discussion, in which several members took part. The great importance of antiseptics in the treatment of all such cases was conceded.

Dr. Holmes, of Chatham, read a paper on "Puerperal Fever," the conclusion of which was that damp air will cause this complaint.

Dr. John H. Packard, of Philadelphia, read a highly instructive paper on

OUR VIEWS OF THE SURGEONS OF THE LAST CENTURY.

The writer dealt principally with Heyster, Pete, and Pott, and showed an intimate acquaintance with their writings, as well as the writings of the other leading surgeons of that time.

He pointed out the many resemblances between the books of that time and those of the present day.

The Association adjourned shortly after eleven o'clock.

THURSDAY, JUNE 9TH—SECOND DAY—MORNING SESSION.

The President, Dr. J. H. Richardson, took the chair at nine o'clock.

Before the programme for the session was taken up, the following question was put and discussed:

IS THE CONTINUED EMPLOYMENT OF LARGE DOSES OF FLUID EXTRACT OF ERGOT LIKELY TO BE INJURIOUS WHEN EMPLOYED IN CASES OF FIBROID TUMORS OF THE UTERUS WHEN OPERATION IS INADMISSIBLE?

The opinions expressed concurred that no injurious effects were produced.

Dr. Lett, of Guelph, was then called upon to read a paper on the question,

WHAT IS THE RELATION BETWEEN MENTAL DERANGEMENTS AND MASTURBATION?

Dr. Lett referred to the want of accurate data in determining the results of masturbation and its influence on the mental powers. He combated many of the popular ideas on the subject, and was of the opinion that in the greater number of cases of insanity attributed to this vice predisposing causes co-operated. A long discussion ensued, in which the positions laid down by Dr. Lett in his paper were generally sustained.

SURGICAL SECTION.

Dr. Strange, of Toronto, read a paper opening a discussion on surgery, and dealing specially with

POINTS IN THE MINOR SURGERY OF THE GENERAL PRACTITIONER.

The use of the knife in minor cases was strongly advocated, and emphasis was put on the application of crucial incision in cases of disease. The paper was concise, able, and of a highly practical character.

Dr. Murray, of Thorndale, asked whether it was customary to give chloroform in minor cases, and several members gave an account of their experience in the use of means to deaden or alleviate pain.

Dr. Powell, of Ottawa, took issue with Dr. Strange in the matter of free use of the knife, on the ground that hemorrhage frequently penetrated the healthy tissue behind the diseased structure on the latter being pierced, and thereby a disease was conducted deeper into the subject.

The President, Dr. J. H. Richardson, warmly complimented Dr. Strange on the ability displayed in his paper, and urged the importance of using the knife in cases of carbuncle and other tumors from blood-poisoning. He also stated his practice of making a copious use of alcoholic stimulants in such cases. He said a bottle or a bottle and a half of brandy per day, for an adult patient, and a bottle of port wine per day to a child were nothing extraordinary, and had been followed by the best results.

Dr. Gerster, of New York, said common-sense had a more important place in treatment than was sometimes accorded to it.

While he agreed with the spirit of the paper, he would not go so far as to state that in all cases caustics should give way to the knife. Circumstances must always determine the particular course to be adopted. One thing he wished particularly to refer to was the abuse of poulticing. It were better in many cases to dispense with the poultice after operation; but it was necessary that patients should be urged to a proper use of it when it was applied.

Dr. Graham, of Toronto, read a paper on a recent case of herpes zoster, including a report by Mr. McCallum, of the School of Practical Science, and the session adjourned for two hours.

AFTERNOON SESSION.

THANKS FROM THE QUEEN.

THE PRESIDENT took the chair at two o'clock. The following cablegram, addressed to Dr. White, Secretary, was read; "The Queen thanks the members of the Ontario Medical Association for their kind congratulations. —PONSONBY."

A telegram was also read from the American Medical Association, and conveying to them their sympathy and good-fellowship.

DR. GEIKIE presented, for the inspection of the members, a tape-worm having its head complete. The specimen was examined with interest, as the head of the tape-worm is not very often seen.

DR. W. H. PORTER, of New York, read a paper,

ON THE ETIOLOGY AND PATHOLOGY OF INCREASED BODILY HEAT IN RELATION TO DISEASE, AND THE USE OF ANTIPYRETICS.

He said that, physiologically speaking, animal heat was produced by the motor forces, or the kinetic energy being converted into heat, or by the universal molecular friction of the microscopic elements of the body. The larger amount of heat, however, was produced by the transformation of the chemical elements of the food, which had a large amount of potential energy which was given off in the form of heat. He referred to the various temperatures, and to some means of determining the causes from which changes of bodily temperature arose.

Drs. Temple, Turver, Cronyn, and Covernton spoke on the subject of the paper.

DR. SATTERTHWAITE, of New York, was then called upon to read his paper on the

SO-CALLED URIC-ACID DIATHESIS,

which was a long and able exposition of the subject, but was not followed by discussion.

Dr. Joseph Workman at this stage entered, and was welcomed by the President as the founder and originator of the Association.

A LARGE GROWTH.

DR. W. H. AIKINS brought in a patient with an unusually large growth on her face for the inspection of the members.

The woman was seventy-three years of age, and the growth, which began twenty-three years ago, weighs from four to five pounds. Dr. Aikins intimated that it was to be removed by operation this morning, when a number of members will attend.

A paper by Dr. Ryerson, of Toronto, on

OPHTHALMIC EPILEPSY,

was, on the motion of that gentleman, held as read, owing to want of time during that sitting.

A paper on

THE REMOVAL OF THE UTERINE APPENDAGES

was read by DR. ADAM WRIGHT. He gave examples of cases occurring in the General Hospital, Toronto, and discussed the application of the operation of removal to three varieties of conditions. In nervous diseases alone, he thought it unjustifiable, as a rule; in fibroid tumors, when hemorrhages endangered life, he approved of the operation. In diseases of the tubes and ovaries, including hydro-salpinx, pyo-salpinx, and hæmato-salpinx, the operation, he said, should be performed in certain cases. He reported several successful operations in illustration.

DR. TEMLPE remarked that the diagnosis was, as a rule, more difficult than Dr. Wright seemed to think. Tubes might be affected with disease without evident enlargement.

DR. R. W. POWELL, of Ottawa read a short paper on

PELVIC HÆMATOCELE,

being a description of a case occurring in his practice in Ottawa, in which pelvic hæmatocele was successfully removed without any operative procedures, through the efforts of nature. The case was of an unusual character, and an appreciative criticism of the paper followed.

DR. PALMER, of Toronto, explained the intubation of the larynx, and answered a large number of questions on his novel and apparently reasonable method.

REPORT ON ETHICS.

The report of the Committee on Ethics was read by DR. J. E. WHITE, the Secretary. The committee expressed the opinion that there are few, if any, members of the Association who do not possess the ethical knowledge, the sense of honor, propriety, and justice which should at all times govern the conduct of gentlemen, and especially members of the medical profession, in their conduct toward each other, toward their patients, and toward the public at large. The committee recommended that the President, Vice-Presidents, and Secretary of the Association be a standing committee to whom any alleged breach of ethics by a member might be referred. Recognizing the influence of local medical associations for promoting intellectual and scientific inquiry and for the securing of correct observance of medical ethics, the committee urged upon the members of the Ontario Association the wisdom of keeping alive and strengthening the various local associations, both with a view to their acting as feeders to the central society, and of being nuclei for the dissemination of medical ethics throughout the province. The adoption of the report was deferred till the evening session, and the sitting adjourned.

EVENING SESSION.

THE PRESIDENT took the chair shortly after eight o'clock.

PRIMARY TUBERCULOSIS.

DR. MCDONAGH, of Toronto, read an interesting paper on "Primary Tuberculosis of the Larynx." The paper expressed the belief that laryngeal tuberculosis, sometimes, at least, if not always, existed prior to pulmonary tuberculosis. He cited one case which had come under his own notice where the patient suffered from hoarseness. A careful physical examination of the lungs did not indicate that those organs were affected. A camel's-hair tube was passed over the larynx, and a microscopic examination of the mucus showed tubercular bacilli. He also had the opportunity of making a post-mortem examination of a subject at the hospital, wherein the lungs were free from tubercular disease, but, on the other hand, the larynx was affected with tuberculosis. The practical value of the establishment of this fact would be that it would be easier to get at the disease in the larynx than when it reaches the lungs.

Several questions were put to Dr. McDonagh as to his treatment of laryngeal tuberculosis, which he answered very fully.

INTUBATION *vs.* TRACHEOTOMY.

DR. PALMER opened the discussion of this question and exhibited the instruments for the performance of intubation. An animated discussion followed on the respective values of tracheotomy, intubation, and simple medication in the treatment of croup.

PUBLIC HEALTH.

DR. SHAW, of Hamilton, presented the report of the Committee on Public Health. The report favored the placarding of houses where infectious diseases existed, and the exclusion of children from school for at least twenty-eight days after infection from diphtheria, and forty-nine days after scarlet fever.

REPORT ON ETHICS.

DR. J. E. GRAHAM, of Toronto, presented the report of the Committee on Medical Ethics.

The committee recommended the adoption of the code of ethics of the American Medical Association, with the amendments which their special circumstances might demand. The most important of these he quoted as follows: "It is derogatory to the dignity of the profession to resort to public advertisements or private cards or handbills inviting the attention of individuals affected with particular diseases, publicly offering advice and medicine to the poor gratis, or promising radical cures, or to publish cases or operations in the daily prints, or suffer such publications to be made, to invite laymen to be present at operations, to boast of cures and remedies, to adduce certificates of skill and success, or to perform any other similar acts. These are the ordinary practices of empirics, and are highly objectionable in a regular physician."

Another clause ruled that no one can be considered as a regular practitioner or a fit associate in consultation whose practice is based on an exclusive dogma, to the rejection of the accumulated experience of the profession and of the aids actually furnished by anatomy, physiology, pathology, and organic chemistry, while, at the same time the good of the patient is involved, such a man, if recognized by the Medical Association, should not be fastidiously refused from fellowship or consultation. The report went on: "Another matter which comes under this head we would here mention—namely, the injustice of the present system of club practice. In this province benefit societies are increasing in number every year, and the fees given for medical attendance are, in most cases, quite inadequate. Your committee think it might be well for the Association to give their opinion on this subject."

On the motion for the adoption of this report, Dr. Ross condemned club doctoring as commonly carried on. The proper way for a physician to do in regard to such societies was to charge, in the regular way, a moderate fee for each patient attended.

Dr. Oldright pointed out that a specialist might be excused for advertising his specialty for the purpose of notifying the public that he did not wish for general practice.

Dr. Burnham argued that his experience showed that it was not even necessary for a specialist to advertise his specialty on the door-plate to escape demands for general practice. He had never done so; and even at first he was very seldom troubled with such calls, and later on not at all.

Dr. Burnham's remarks were evidently popular with the assembly as he was frequently applauded.

The report was adopted.

MEDICAL DEFENCE UNION.

Dr. Henderson introduced the report of the committee appointed to consider the question of a medical defence union, as follows: "The committee appointed to report on the motion of Dr. Henderson, regarding the formation of a medical defence union, beg to report that in their opinion it is desirable to appoint a committee whose duty it would be to consider appeals from members of this Association who may consider themselves persecuted by unfounded and malicious accusations. If requested, this committee will give professional advice to any member of this Association who may be defendant in a case of surgical malpractice, the Advisory Committee to consist of Dr. Moore, Brockville; Drs. Sullivan and Henderson, Kingston; Dr. Day, Trenton; Dr. Malloch, Hamilton; Drs. Thorburn, Richardson, and White, Toronto; Dr. Eccles, London; Dr. Harrison, Selkirk; Dr. Taylor, Goderich; Dr. Thorburn, chairman of the board."

The report was adopted.

OFFICERS ELECTED.

The Nominating Committee brought in the following nominations of officers for the following year:

President—Dr. J. W. Rosebrugh, Hamilton.
First Vice-President—Dr. H. M. McKay, Woodstock.
Second Vice-President—Dr. Moore, Brockville.
Third Vice-President—Dr. Adam Wright, Toronto.
Fourth Vice-President—Dr. Taylor, Goderich.
General Secretary—Dr. J. L. White, Toronto.
Treasurer—Dr. N. A. Powell, Toronto.
Corresponding Secretaries—Dr. Fenwick, Kingston; Dr. McPhatter, Guelph; Dr. R. W. Powell, Ottawa; Dr. Shaw, Hamilton.

It was decided to meet in Toronto next year.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

ANTIPYRINE IN RHEUMATISM—PATHOLOGY AND TREATMENT OF EPISTAXIS—STUDIES OF TUBERCULOUS AND TYPHOID BACILLUS.

Paris, June 5, 1887.

Professor Germain Sée, who, it will be remembered, so much extolled the efficacy of the salicylate of soda, and contributed so much toward generalizing the use of this remedy in the treatment of acute rheumatism and acute gout, as well as in other febrile affections, has found a good substitute for it in antipyrine, discovered about three years ago by Knorr, who then introduced it as an antithermic remedy. Professor Sée, however, has since discovered that, besides this hypothermic property, antipyrine is a powerful analgetic, and, in a communication recently made by him to the Academy of Sciences, he stated that, of fifteen patients affected with rheumatism without fever, and accompanied or not with hydrarthrosis, who had been unsuccessfully treated by the actual cautery, the salicylate of soda, the pain, with the articular engorgement, disappeared in a few days by the use of antipyrine, without any relapse. The same effects were observed in attacks of acute gout, whether these were grafted or not on the chronic form with lithic deposits. Antipyrine was administered in doses of from four to six grammes per day, but to insure the good effects of the remedy it must be continued in small doses for at least a week after the disappearance of the symptoms. But it is not only in these affections that Professor Sée found antipyrine useful, but it is invaluable in all cases, whatever be their nature, where pain is the predominant symptom. He finds antipyrine superior to antifebrine. It leads to the same results without producing any injurious effects on the heart and kidneys. He noticed, however, that when strong doses are administered, or when the medicine is continued for any time, an eruption resembling urticaria or scarlatina has been noticed, which, however, disappears on reducing the quantity of the drug, or discontinuing it. Antipyrine is eliminated unchanged by the urine. In bleaching the latter by charcoal, its presence may be detected by the aid of the perchloride of iron, which communicates a deep red color to the urine, and that during one or two days after the cessation of the medicine.

Professor Verneuil was evidently born a physician, but the fates have made him a surgeon, if one may judge from his tendencies toward medicine. This he has shown on many occasions, and at a recent meeting of the Academy of Medicine he expatiated on the pathology and treatment of epistaxis, the mechanism of which he connects with disease of the liver. He does not pretend to have been the discoverer of this fact, as he traces back the idea to Galen, who, he said, cured epistaxis by the application of dry cupping to the hepatic region. Following up this idea, M. Verneuil, in treating three cases that came under his observation, and after having failed with the usual remedies employed to arrest bleeding from the nose, applied a

large blister to the hypochondrium, which had the effect of immediately arresting the hemorrhage. M. Verneuil attributed the cure in these cases to the revulsive effect of the blister. But, remarked one of the members present, this happy result may be obtained by the application of a revulsive to any part at a distance from the seat of hemorrhage. Some of the members requested M. Verneuil to explain the *rationale* of the treatment he had employed in these cases. To this he rejoined that he could give no explanation, but that he was sure that the facts observed by him, which were clinical, were not simple coincidences, though he was not able to put any interpretation on them. What other members said did not throw much light on the subject, so I need not trouble your readers with their statements.

Among other proofs of Professor Verneuil's predilection for medicine I may here note that a kind of collective investigation of tubercle has been originated by him, under the title of "Œuvre de la Tuberculose," in which he is assisted by Drs. Bouchard, Brouardel, Charcot, Cornil, and others. The object of the work is to collect evidence of every kind bearing on the subject. The first instalment of the labors of these investigators has just appeared in a fasciculus of three hundred and fifty pages, under the title of "Études expérimentales et cliniques sur la Tuberculose." The work begins with a notice by Dr. Thaon, of Nice, on the subject of tuberculosis. Professor Cornil contributes an article on the phenomena of karyokinesis observed in tuberculosis, which, according to the author, is determined by irritation due to the penetration of Koch's bacillus into the cells. Dr. Gosselin, of Caen, has endeavored to discover a method of attenuating the virus of tuberculosis, while Drs. Raymond and Arthaud have tried to render animals refractory to the disease, but with what success the authors do not mention. Drs. Landouzy and Martin have treated of the hereditary side of the question, without, however, materially influencing the pros and cons of the case. The morbid and surgical pathology of tuberculosis have been studied by Drs. Reclus, Valude, and Verneuil. The different methods of treatment are also dealt with by various writers. On the whole, the work is worthy of perusal, though it cannot be said that the authors have greatly elucidated the pathology of tuberculosis; nor have the therapeutics of the disease been much advanced by their contributions.

In a paper communicated to the Academy of Medicine, the author, M. Gabriel Pouchet, gives the results of his researches on the conditions of the development and preservation of the typhoidic bacillus. His conclusions are almost in opposition to those entertained, till now, by other investigators, who considered that fecal matter was the most favorable vehicle of the contagium of typhoid fever. According to M. Pouchet, the proliferation of this curious bacillus is arrested in media rich in organic matter, whatever be its nature. It is preserved and developed much better in clean than in foul water. This fact would seem to be in contradiction to the conclusions arrived at by Dr. Brouardel, as expressed by him in his report to the Academy of Medicine on the recent epidemic of typhoid fever at Pierrefonds, when he attributed the cause to the infiltrations of organic matters into the water which served for drinking. So it was with the report of Drs. Cornil and Chantemesse, on certain epidemics of typhoid fever which lately occurred in the barracks of the firemen of Paris, who saw in the bad quality of the water used by these men the same relation of cause and effect. More recently, Dr. Thoinot, who had made laborious researches to discover the typhic bacillus in the foul waters of the Seine, found that the pure drinking-water of the Vanne, which supplies a considerable part of Paris, contains the bacilli in much larger numbers.

Dr. Bergeron has been almost unanimously elected to succeed the late Professor Béclard, as perpetual secretary to the Paris Academy of Medicine.

ACETONÆMIA—WHY?

To the Editor of The Medical Record.

Sir: An article in The Record of April 16th, entitled "Three Cases of Acetonæmia," ends as follows: "Though instances are recorded of recovery out of even coma itself, yet these are too rare to alleviate the extreme gravity of the outlook when once the urine turns red with ferric chloride." On page 255 of vol. ii. of the "Reference Handbook of the Medical Sciences," under the title of "Coma Dyspepticum," we read: "The urine had that fruity smell of the diabetic urine, and gave the same characteristic reaction with ferric chloride. . . . This condition lasts from two to three days, when the somnolency and also the fruity smell of the urine gradually disappear, recovery taking place in a few days." Here you find the same conditions of the urine as regards acetone in a simple dyspeptic coma and in a grave diabetic coma—in the one, recovery taking place in a few days; in the other, death occurring equally soon. We therefore conclude that the Burgundy-red color of the urine, with ferric chloride, does not necessarily present so grave an outlook as one might be led to believe from the conclusion of the article of April 16th.

A few words relative to acetone, and my experience with it. Some years ago acetone gained some little notoriety as a remedy in pulmonary affections, my attention being called to it some years since by an old physician who had long used it in cases of lung and bronchial affections. I have, at various times since, made use of it in such instances, deriving marked benefit from it in numerous cases, in the way of lessening the severity of night-sweats, quieting cough, and causing expectoration. I have given it in doses ranging from one-half to two drachms twice, thrice, or four times daily, and yet I have never seen coma occur, though in many cases I have administered it for months at a time. While a patient is taking it the urine, after standing a few hours, has a strong fruity odor, and the breathe very frequently has the characteristic odor.

In those cases which occur so frequently, among children and old and feeble people, of stomach derangement, and which are less severe conditions of the same disorders which produce "coma dyspepticum," the body, breath, and urine always have that same fruity odor; but these patients do not die comatose, nor do they present any particular nervous symptoms. I have tested the urine in many such cases, and found it to contain acetone, and to furnish the characteristic color with liquor ferri perchloridi.

Since reading the article of April 16th I obtained three fair-sized rabbits, and gave them acetone in large quantities, but was unable to produce coma or any nervous symptoms other than a little excitement when first administered. After continuing its use for ten days, in doses from one to six drachms, three times daily, the rabbits were in as good condition as when I began with them, except that they each suffered from a catarrh of the bowels, the usual "ball passages" being softer than normal and covered with mucus.

If acetone produces coma and death in diabetes, why will it not produce coma and death in stomach derangements of children and old people, or when administered by the mouth or hypodermically, and why will it not produce death in "dyspeptic coma?" In all of these conditions the system is supercharged with acetone, and the urine turns red with "ferric chloride."

With so little evidence on which to build the name "acetonæmia," and almost nothing to prove that "acetone" produces coma, is it not preferable to still cling to the old name, "diabetic coma," which, with uræmic

coma, fully explains the general conditions of the two great forms of coma, and which never need be confounded if the four cardinal differences be remembered, viz.:

Uræmic Coma.	*Diabetic Coma.*
Convulsions.	No convulsions.
Urine scanty.	Urine excessive.
Urea diminished.	Urea unchanged.
Albumin.	Sugar.

F. E. MAINE, M.D.

AUBURN, N. Y., May 17, 1887.

"THE DOCTOR'S SUMMER PRACTICE."

TO THE EDITOR OF THE MEDICAL RECORD.

AN editorial in a recent number of THE MEDICAL RECORD suggests an answer to the question in a former number of the same publication, "Do country doctors think?" Oh, yes; the younger members, especially, do an immense amount of thinking. Too often the days are not long enough for them to finish their thinking, and they are obliged to lie awake at night for that purpose—the burden of their thoughts being the all-important question, Where is the next barrel of flour coming from?

After years of hard work, having no thought of rest or recreation, having "borne the heat and burden of the day" and the cold and storm of the night, having gained a reputation and a name, and settled the flour question, we are confronted with a new horror.

The city practitioners are advised to swarm down upon us like the locusts of Egypt. The average rural mind has become imbued with the idea that any and every city physician is a monument of knowledge, and that what he does not know is not worth knowing; which, in the words of the immortal Lincoln, "reminds me of a little story."

It happened in old Twenty-third Street College, at Professor Willard Parker's clinic. Many of your readers will remember that Professor Parker took great pleasure in diagnosing his cases without any "fuss and feathers." The greatest interest of those days was to see Professor Parker diagnose without going near the patient, and Professor James R. Wood operate against time. Upon this occasion the patient was an old Irishwoman, and after the professor had walked around her two or three times, and made a few remarks upon general topics, he gave her a detailed description of all of her symptoms and the order in which they had appeared. Her reply, which brought down the house and made the roof rattle, was, "Oh, Dr. Parker, what you don't know isn't worth knowing."

And now we are informed that the city physician requires a change, and that he proposes to practise in the country during "the season." In all directions from New York are many pretty little villages, at sea-shore and on mountain, which are known as summer-resorts. They have a permanent population of from one thousand to five thousand. The physicians who practise in these villages count upon "the season" as their harvest-time.

Some years since your correspondent spent his vacation at a noted resort on the New Jersey shore. The first fact which attracted his attention was that nearly every house had a doctor's sign attached. In that instance they were mostly from the country, rural practitioners who wanted sea-air and took their shingles along. One day a little boy fell out of a boat. He was soon brought ashore, but before he got there there were six physicians waiting for him. One, more eager than the others, walked into the water, captured, and carried him off. Those left without a patient were compensated by the subsequent information that only his clothing was injured, and that he was the son of a poor washerwoman.

Now, to avoid any such scenes in the future, I would suggest that a fair exchange is no robbery, and that a change would be desirable for the village doctor. Let us exchange offices for the summer. We could attend to the head of the family and the workers who do not migrate, and also visit the hospitals and attend the polyclinics, and return to our homes in the fall fully as much benefited as the city physician. A. B. L.

BABYLON, N. Y.

PICRATE OF AMMONIA IN MALARIAL FEVERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your issue of May 7th contains an article by Dr. Martyn Clark, copied from the London *Lancet*, advocating the use of picrate of ammonia in all malarial diseases of an intermittent character. Having been for many years a sufferer from chronic malaria, and being at the time afflicted with an unusually severe attack, for which I had taken the usual remedies without receiving any benefit, I at once procured some of "Merck's" picrate of ammonia, and began its use in half-grain doses (made into a pill with extract of gentian) three times a day. In three days' time there was marked improvement in all my symptoms. Had no more chills, pain in head and back had left me, and I awoke in the morning without those terribly exhausted and irritable feelings which those who suffer from this disease so well know. This result encouraged me to make trial of the drug in several cases of similar trouble in which I had been using quinine, etc. I prescribed it for six adults, of both sexes, and kept watch of the effect. In all but one case the same marked improvement speedily resulted. I now began to notice a peculiar, deep-orange color in my urine, without any change in quantity, and a chemical analysis of it showed that except for the change in color it was normal. Upon inquiry I found that the urine of all the patients was of this same orange color. Having taken the medicine myself in doses as above mentioned for ten days, I decided to stop its use and watch for the disappearance of this color from the urine. To-day, May 24th, seven days since stopping the medicine, there is not the least improvement in the color of my urine, and the whites of my eyes, and the skin of my face generally, are the color of one mildly jaundiced. The same thing has occurred to all my patients who have taken the remedy for a week. One lady, to whom I gave the maximum dose, one and a half grain three times a day for eight days, is now deeply jaundiced, the color involving not only the whites of the eyes and the skin of her face, but also the skin of her neck and breast, from which, shading to a lighter color, it covers the rest of her body. In each case the tongue is clean, bowels not affected, and appetite good. I do not understand why the discoloration of the urine remains so long after stopping the medicine, or why it should cause discoloration of the skin at so late a day. Hoping that some of your readers may be able to inform me as to the length of time this picric-acid discoloration is likely to last,

I remain, truly yours,

S. E. FULLER, M.D.

77 HANSON PLACE, BROOKLYN.

DEATH FOLLOWING INTERNAL URETHROTOMY.—Internal urethrotomy is so seldom followed by untoward results that the case reported by M. Jobard to the Surgical Society of Paris at their meeting on February 23, 1887, is of much interest. M. Jobard performed internal urethrotomy for a traumatic stricture, and the case presented no unusual incident, except a rather free bleeding. The evening of the same day he was recalled to see his patient, who was dying, death resulting that night.—*Medical Press.*

New Instruments.

A FOLDING ALLIS ETHER-INHALER.

By GEORGE R. FOWLER, M.D.,
BROOKLYN, N. Y.

ALTHOUGH many surgeons still prefer the ordinary folded napkin or improvised cone method of administering ether, yet there can be no doubt as to the advantages to be derived from the use of a specially devised apparatus like the Allis inhaler. In it are combined simplicity of construction, ease of manipulation, rapidity of etherization, economy of ether and a free ingress of atmospheric air charged with ether and egress of expired air. It is open to the objection, though to a less extent than other instruments of its class, of being somewhat cumbersome when carried about, and of occupying, therefore, considerable space in the operating-satchel. My attention was forcibly directed to this point when devising an emergency operating-bag recently. I have therefore endeavored to overcome this objectionable feature by slightly altering the shape of the inhaler in such a manner as to allow of its being folded flatwise. The accompanying cuts will show how this is accomplished. Fig. 1 represents the

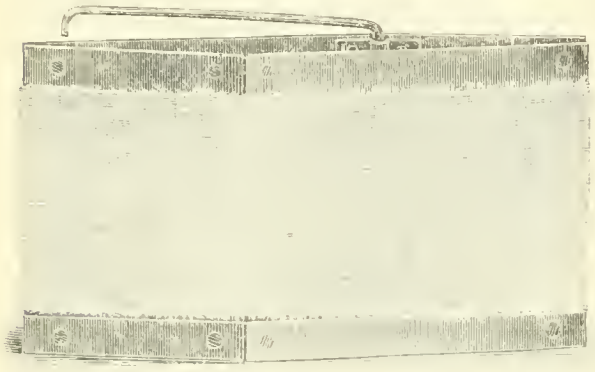


FIG. 1.

inhaler folded, ready for placing in the pocket or satchel, in which shape it occupies about as much room in the pocket or satchel as an ordinary visiting-list. By a very simple movement, provided for by bringing together the corners of the metal sides, the two long sides are made to separate from each other, until the shape shown by Fig. 2 is formed, in which position it is securely held by

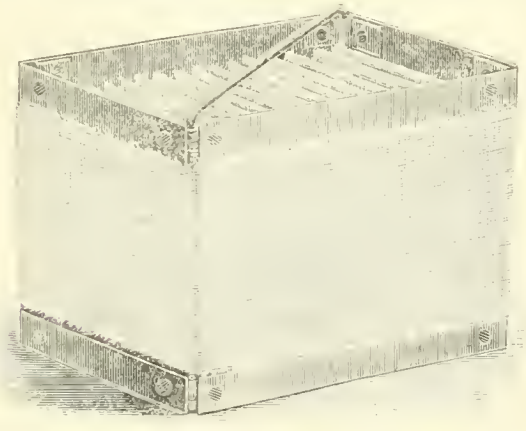

FIG. 2.

a little bar which swings over from one corner to the one diagonally opposite, and fastened, by its bent extremity, into a socket provided for the purpose.

The only covering needed for an Allis inhaler is a simple towel folded lengthwise, in which the instrument is inclosed just prior to its use. This can be procured at the patient's house, and, after the operation, unpinned and thrown aside.

A SELF-RETAINING SPECULUM.

By CLEMENT CLEVELAND, M.D.,
NEW YORK.

THIS instrument is designed as a so-called self-retaining speculum. It consists of two Sims blades, each with a flange and separated by an interval of one inch and three-fourths (Fig. 1). These, though in parallel planes, look-

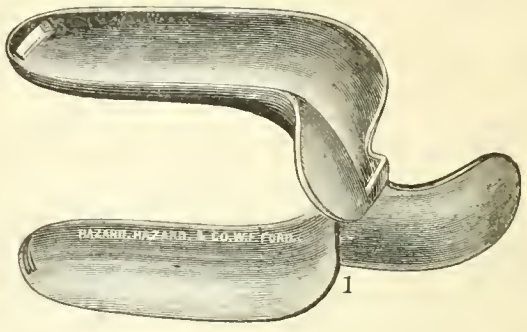

FIG. 1.

ing at them from the side, will be seen to be at a slight angle to each other when held with the concavity of either toward the observer, the nearer blade deflected to the right and the farther one to the left. The object of this will be explained further on.

At the point of each blade is a fenestra, and at the bend of the instrument, where the two blades come together, is a narrow metal band. To complete the instrument there is a belt of webbed material to be applied about the waist. On this is looped, to admit of its being moved readily to any position upon the belt, a piece of the same material. To this is attached a long leather strap, with oblong perforations placed at intervals of half an inch. At the point where this strap and the piece of belting are joined there is a hook, the purpose of which will appear later. (See Fig. 2.)

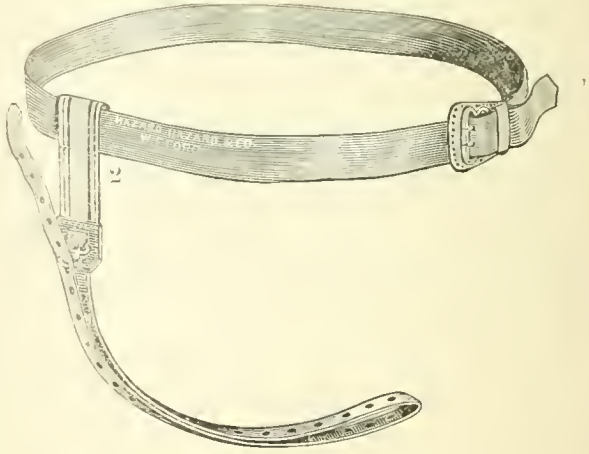

FIG. 2.

To apply the instrument, the belt is first buckled by the patient, not tightly, about her waist and outside of her clothing, with the attached strap behind and the hook turned outward. She is then placed in the Sims position. The operator selects the blade he thinks better suited to the case, and holding the instrument with the right hand, with the left he passes the leather strap through the fenestra at the point of the other blade and then under the metal band, leaving the strap quite loose between them. Then holding the speculum still with the right hand, with the index-finger extended along the concavity of the blade, it is introduced, care being taken to pass it back of the cervix. The instrument is then pushed firmly up against the perineum, the outer blade reaching a point just at the bend of the coccyx. I would say here, in parentheses, that I have tried

the instrument in over fifty women in my clinic at the Woman's Hospital, and find that the interval of one inch and three-fourths between the blades is enough, even in the stoutest women, to include all tissue between the posterior wall of the vagina and the integument between the nates. In very thin women it will even be found advisable to place a folded towel under the external blade. The next step is to draw the leather strap tight, first through the fenestra and then under the metal band. The perineum is then retracted to the required degree by drawing the strap backward and securing it to the hook provided for the purpose and above described. By now using the vaginal depressor the cervix is brought at once into view.

When the belt is applied outside the dress it may be necessary to pass the strap through the fenestra at the end of the blade. In many cases the clothing, pushed back from the buttocks, is bunched up so high that it is necessary to have the tension exerted from the two points. If the tension were from the metal band alone the speculum would be more likely to pull out. When the belt is applied merely over the night-dress, as in an operation, then it may be only necessary to pass the strap under the metal band, for then the tension is directly backward and the speculum cannot possibly pull out, as the strap presses firmly over the point of the blade. Still I should advise its always being passed

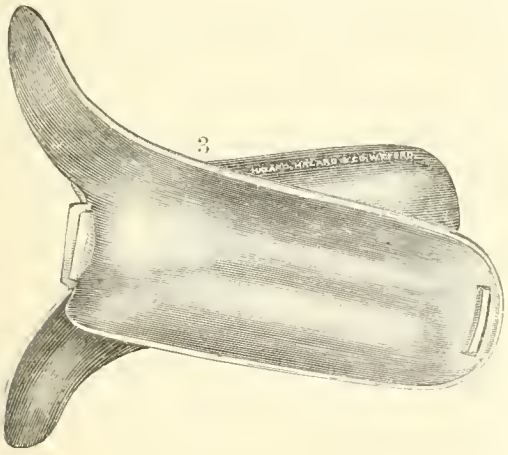

Fig. 3.

through the fenestra. This I will explain below. To remove the speculum, detach the leather strap from the hook. The oblong perforations enable the operator to pull the strap off with the greatest ease. Then the speculum is withdrawn from the vagina and off of the strap at the same time.

I should here explain why the blades are placed at an angle to each other, as above described. The chief fault to be found with all self-retaining specula is that, to see at all satisfactorily, one has to stoop; while with the Sims speculum, held by a nurse, we look directly down upon the cervix as we sit before the patient. This is because the nurse does not pull directly backward upon the perineum, but a little upward, thereby tilting the point of the blade a little downward. This is precisely what is accomplished by giving the aforesaid angle to the blades in this new speculum, the strap pulling the outer blade directly backward, thus tilting the other just enough downward. (See Fig. 3.) If the strap is not passed through the fenestra there is danger that the point of the blade under the strap may slip upward, and especially so in thin women, thus deranging the position of the blade in the vagina.

The instrument seems to possess several advantages which it may be well to mention. In the first place, it consists of two blades of different size. It is simple, having no mechanism about it to get out of order. It can be easily kept clean, being entirely of metal and in one piece. It does the work at least as well as, and is cheaper than, any speculum yet devised for the purpose, costing, probably, not more than $3, or $3.50.

It is not claimed that it can take the place of a well-trained nurse, but it certainly does better than an indifferent one. It has been used in several cervix operations at the Woman's Hospital, with entire satisfaction to the operator.

The instrument was made for me by Mr. W. F. Ford, of the Instrument Department of Hazard, Hazard & Co., of this city, and is in several sizes.

59 West Thirty-Eighth Street.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 19 to June 25, 1887.

Sutherland, Charles, Colonel and Surgeon. Granted one month's leave of absence, with permission to apply for an extension of one month. S. O. 126, Division of the Atlantic, June 23, 1887.

Smith, A. K., Lieutenant-Colonel and Surgeon. Will be relieved from duty at West Point, N. Y., on September 30, 1887, instead of on August 28, 1887. S. O. 144, A. G. O., June 23, 1887.

Alden, C. H., Major and Surgeon. Leave of absence extended to include September 29, 1887. S. O. 144, A. G. O., June 23, 1887.

Bartholf, J. H., Major and Surgeon. Granted leave of absence for two months, to take effect about July 5, 1887. S. O. 141, A. G. O., June 20, 1887.

Richard, Charles, Captain and Assistant Surgeon. Sick-leave extended two months on surgeon's certificate of disability. S. O. 139, A. G. O., June 17, 1887.

Cochran, John J., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 143, A. G. O., June 22, 1887.

Sutro, William N., First Lieutenant and Assistant Surgeon. Designated as Medical Officer for the Rifle Camp at Creedmoor, N. Y., July 5, 1887. S. O. 124, Division of the Atlantic, June 21, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending June 25, 1887.

Cleborne, C. J., Inspector. Ordered for examination preliminary to promotion as Medical Director.

Lumsden, G. P., Passed Assistant Surgeon. Ordered to receiving-ship Franklin, Norfolk, Va.

Hornitz, P. J., Medical Director. Permission to leave the United States for six months.

Harris, H. N. T., Assistant Surgeon. Commissioned Assistant Surgeon in the Navy, June 13, 1887.

Spear, J. C., Medical Inspector. Detached from Naval Laboratory and granted three months' leave.

Bloodgood, Delavan, Medical Director. Detached from Naval Hospital, Norfolk, Va., and ordered to Naval Laboratory.

Bradley, Michael, Medical Inspector. Ordered to Naval Hospital, Norfolk, Va.

Beyer, H. G., Passed Assistant Surgeon. Remain on present duty until September 1, 1887.

Herndon, C. G., Passed Assistant Surgeon. Remain on present duty until June 17, 1888.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 18, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	4
Scarlet fever	69	10
Cerebro-spinal meningitis	4	4
Measles	37	5
Diphtheria	127	56
Small-pox	2	1
Yellow fever	0	0

Is Iodoform Antiseptic?—The widespread employment of iodoform as an antiseptic dressing may receive a check should the conclusions arrived at by MM. Heyn and Rovsing, of Copenhagen, be confirmed. These observers have been making experiments with iodoform to test its value as an antiseptic, which they point out is so generally accepted that the surgeon does not hesitate to employ a non-sterilized spatula or to insufflate ordinary air with the powder procedures which he would shrink from employing were it not for the belief that the iodoform can destroy the germs adhering to the one or suspended in the other. Yet as iodoform is rarely used to the exclusion of other antiseptics (as carbolic acid or mercuric chloride), there is never much opportunity, clinically, of testing its germicidal properties. Mikulicz, in 1881, tested the action of iodoform upon putrefaction, with no definite result; and Rummo's experiments, in 1883, were complicated by his use of oil of turpentine as a solvent for the iodoform. Meyer found in one case of abscess that iodoform had no effect in reducing the virulence of the pus, and in another that it had a slight action. The results of the research pursued by MM. Heyn and Rovsing surprised themselves. Acting on the theory that it is through liberation of free iodine that iodoform enjoys its germicidal reputation, they prepared solutions of iodoform in olive-oil and in serum, and, having sterilized them, mixed them with culture media, and studied the effect of cultures of various bacterial organisms in these mixtures, as well as under iodoform powder alone. They also experimented on rabbits by mixing inoculation fluids with iodoform. The details of the experiments need not be reproduced here; suffice it to say that in no case did the presence of the substance interfere with the development of micro-organisms. So that they conclude that as an antiseptic its employment in surgery is valueless. But, more than this, its use is dangerous, for, as two of their experiments proved, iodoform itself may contain pathogenic micro-organisms; and even if all care be taken to purify it, yet it may become the medium of the conveyance of pathogenic germs introduced into it through the spray or spatula. We trust that these experiments, which have received such prominence, will be repeated, for, if confirmed, we can imagine that the use of iodoform (apart from any other antiseptic) would in certain circumstances be serious. It would be deplorable if in any such case the material upon which the surgeon relies to protect his patient from bacterial invasion should prove to be the means whereby such invasion occurred. The writers of the article themselves advise that before using iodoform (which is valuable as a dressing on other grounds than as an antiseptic only) it should be disinfected in sublimate solution.—*The Lancet*, February 12, 1887.

Oxalic Acid in Asthma.—Oxalic acid in-two-to five-grain doses has been much lauded by Dr. Poulet, of Planchet les Mines, in the treatment of essential asthma, as well as of emphysematous and bronchitic dyspnœa. He has been using it for five years past, and has never met with any untoward symptoms following its employment, while its effect in relieving the severest dyspnœa has invariably been prompt and certain. Oxalic acid has a strongly sedative action on the heart, and, in toxic doses, kills by producing cardiac paralysis. It is a powerful antipyretic, and also possesses marked emmenagogue properties. In fever larger doses are tolerated than in health, and it has no cumulative action. It should always be given in a very dilute solution, as, otherwise, local irritation of the stomach, etc., may result.

Salol in Sciatica.—Dr. v. Aschenbach, of Corfu, reports in the *Fortschritt der Med.* that, suffering from sciatica, for which all known remedies have been tried in vain, he at last resolved to try an unknown one—to himself, at least, unknown as a remedy for sciatica. In the evening he took a dose of half a gramme, and at midnight one gramme, of salol, after which he fell asleep, and remained perfectly free from his pains.

Cancer of the Stomach.—At a meeting of the Hospital Medical Society of Paris, M. Ferrol brought the case of a patient, aged fifty-six, suffering from cancer of the stomach, in whom the subclavicular glands were infiltrated. This is his fourth case in which he has noted the enlargement of the subclavicular glands in this disease. —*Medical Press.*

The Thermal Death-point of Pathogenic Organisms.—According to Sternberg the following table represents the thermal death-point of various microbes:

Organism.	Thermal Death-point. Deg. Fahr.
Typhoid-bacillus	132.8
Cholera-spirillum (comma-bacillus of Koch)	125.6
Cholera-spirillum of Finkler and Prior	125.6
Cholera-bacillus of Emmerich	143.6
Anthrax-bacillus (without spores, Chauveau)	129.2
Tubercle-bacillus in fresh sputum (Schill and Fischer	212
Bacillus of glanders (Löffler)	131
Bacillus of mouse septicæmia Bacillus of Rouget Bacillus of Schwein-Rothlauf (These three organisms appear to be identical. They are said to form spores.)	140
Brieger's bacillus (from fæces)	143.6
Bacillus of green pus	132.8
Friedlander's bacillus (so-called pneumococcus)	136.4
Bacillus of foul-brood	212
Staphylococcus pyogenes aureus	136.4
Staphylococcus pyogenes citreus	143.6
Staphylococcus pyogenes albus	143.6
Micrococcus of osteomyelitis (Probably identical with Staph. aureus)	136.4
Streptococcus of erysipelas	129.2
Micrococcus tetragenus	140
Micrococcus Pasteurii (Sternberg)	140

Blood-clot and Septic Injections.—Dr. C. E. Nelson, of this city, writes: "In The Medical Record of June 4th, out of many other things to interest, I will pick out merely the subject of the heading of this article. Dr. Wylie has found out that purgation is good in peritonitis, against locking up with morphia; this practice I have already successfully followed for many years without placing it in the journals. Dr. R. T. Morris also thinks that, as in Tait's hands, free purgation answers the purpose of antisepsis and drainage. In The Record's editorial, p. 638, is given the opinion of French surgeons that drainage may be dispensed with when perfect antisepsis is obtainable. Thus we are drifting back, insensibly, to old-time methods before Listerism was introduced. Schede, Morris, and others think that a blood-clot may be advantageously left, as it may organize, if treated antiseptically; another advantage, as also mentioned in the above-mentioned editorial, is that time is gained in not ligating vessels. Following the method of my father, R. Nelson, I have been in the habit of performing operations, tying hardly any arteries, allowing a little bloody serosity to flow, then wait a little, let the wound glaze over by contact with the air, then bring together the skin-flaps, if possible. This makes a *double* protection, the crevices are filled up, and the air excluded by suture, compress, and bandage; no antisepsis or drainage.

RUBELLA (RÖTHELN: GERMAN MEASLES).

With a Report of One Hundred and Fifty Cases.

By J. P. CROZER GRIFFITH, M.D.,

ASSISTANT TO THE PROFESSOR OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA; PHYSICIAN TO ST. CLEMENT'S DISPENSARY, PHILADELPHIA.

(Continued from page 17.)

SYMPTOMS OF THE ERUPTIVE STAGE.—Either appearing with the eruption, or continuing from the stage of invasion when this was present, we find the symptoms of the disease. In the latter case they are simply the prodromes, often more or less intensified. Coming prominently into view is the combination of the catarrhal symptoms of measles with the angina of scarlatina, both, however, in a mild form. This has been noticed by many writers.

In the cases included in this article the most prominent of the *catarrhal symptoms* referable to the nose and eyes was a slight redness and suffusion of the latter. This was the most striking symptom in fully one-half the number of cases, and often even this was absent. In other instances there was sometimes sneezing and lachrymation; not often coryza, and rarely photophobia. A loose, bronchial cough was frequently present, and occasionally demanded treatment. The statements of authors regarding the intensity of the catarrhal symptoms correspond, for the most part, with the description I have given, although some are mutually conflicting and contradictory. Certain writers, as Trousseau and Reed, deny the presence of catarrh; others, as McLeod and Vogel, say there is usually none. According to Burnie, the absence of coryza and cough is a distinctive feature of the disease, but congestion of the conjunctiva is common. Brodie states that there is no sneezing; Douglas that coryza is present in about one-half of the cases, and is less apt to occur than are other catarrhal symptoms; Thomas, that conjunctivitis and sneezing are rarely absent, especially at the beginning of the attack; Kassowitz, that there is catarrh of the eyes and of the nose and sneezing, but cough occurs in very few cases; Wilson, that there is no bronchitis, and Cuomo, that it is usually present; Klaatsch, that there is never marked photophobia or lachrymation; Squire, that the eyes are diffused, and there is little or no coryza; Cheadle says that croup-like cough is common, and that in one case this was so incessant that he was obliged to administer chloroform. Without doubt the severity of the catarrhal symptoms depends somewhat upon the epidemic, yet in nearly all cases it is very slight as compared with measles.

Sore throat is almost universally admitted to be characteristic of rubella, yet it is nearly always much less marked than in scarlatina. In the cases reported here it was invariably present, although generally slight, and the patient made no complaint of it. Examination, however, usually revealed redness of the mucous membrane, particularly marked at the upper portion of the anterior pillars of the palate. Sometimes the inflammation was quite severe, the tonsils were much swollen, and deglutition was painful. The occasional marked swelling of the tonsils, with difficult or impossible deglutition, and with profuse secretion of mucus, has been mentioned by many writers. I know of no writer who has not found sore throat generally present, except Parke, who limits "mild tonsillitis or pharyngitis" to twenty per cent. of his cases. Particular stress is laid upon its almost constant occurrence by Murchison, Liveing, Edwards, Burnie, Hemming, Aitken, Copland, Paterson, McLeod, and very many others. It is, indeed, one of the many diagnostic symptoms of the disease. Thomas claims that, whereas in scarlatina only the posterior parts of the throat are attacked, in rubella the anterior are affected as well. In most of the cases included in this article the throat exhibited a diffuse, even redness, either limited in extent or wide-spread. In a few instances, however, an eruption of small, yellowish-red or brownish-red spots, of pin-head size, was visible over the soft palate and uvula and the inner surfaces of the cheeks. A similar appearance has been described by Emminghaus, Nymann, Gerhardt, Picot, Parke, Dunlop, Kassowitz, Cuomo, and others. Mettenheimer mentions only the evenly diffused redness; Thomas says he has never seen a true punctate eruption in the throat and oral cavity; and Klaatsch claims that it does not occur.

Hoarseness is sometimes present, according to various authors (Thomas, Emminghaus, Edwards, etc.). I can report its presence in some cases, and it has been described as often severe by Aitken, Cheadle, Paterson, and others.

The *duration* of the catarrhal and anginose symptoms already described is said by Thomas to be coequal with that of the eruption. They diminish in intensity as the latter fades. This rule seems to me usually to hold good, though in some instances I have observed entire cessation of the symptoms after twenty-four hours, while the rash had faded but slightly. Emminghaus thinks the symptoms diminish with the temperature rather than keep pace with the eruption.

Squire states that an increase of the catarrhal symptoms sometimes takes place as the eruption disappears. Liveing says the sore throat is apt to persist after the rash has faded. In one of the cases under the care of Dr. Shoemaker, and reported here, sore throat continued for eighteen days from the first appearance of the eruption. I have frequently noticed that the cough lasts after the patient seems in other respects well.

Fever is an important accompaniment of the eruptive stage, concerning which there is much contradictory evidence. As already stated, slight fever may attend the stage of invasion, and, according to Eustace Smith, this is not increased on the appearance of the rash; Roberts and others say it diminishes. Careful daily records were made in the eruptive stage in a large number of the cases reported here, and the results show that some elevation of temperature was almost always present. This was greatest usually upon the first, often on the second, day of the eruption, and subsided gradually with it. The fever ranged up to 103°+ F., although it rarely exceeded 101° or even reached this figure. In a considerable number of cases an elevation of temperature—99.5° to 100°—continued, even after the rash had entirely vanished. Possibly the persisting bronchitis was the cause of this in some instances. In very many cases the temperature fell abruptly to the normal on the second day, while the rash was still at its height or had faded but little. In a few instances in which there had been no fever a slight rise in temperature began when

the rash was nearly gone. No cause for this could be detected. It seems to be analogous to the late development of catarrhal symptoms described by Squire and already mentioned. This author says, too, that the temperature is easily disturbed in the week following the disappearance of the eruption.

Thomas describes the same varying temperature, stating that there may be no elevation at all, or that the curve may fall suddenly or slowly at any time in the disease. Hardaway says that the disturbance of the temperature, if present, is usually limited to the first few hours of the eruption, but that it may continue unabated until the end of the disease. Emminghaus writes that in many cases and epidemics the temperature is not above normal; and in those patients who exhibit fever we find either an initial temperature becoming normal before the disappearance of the eruption, or a continued elevation of temperature throughout its entire duration. Squire claims that the fever subsides with the rash on the third day. Reed says it is never over 101° F., and always falls on the second day; Alexander and Cuomo, that the prodromal fever diminishes when the eruption appears; Burnie, that it rarely exceeds 102°; Vogel, Wunderlich, Earle, and Picot, that there is usually no fever; and J. L. Smith, Barthez and Rilliet, Claussen, Parke, Bourneville, and Bricon, and Tonge-Smith, that it is slight if present. The writer last mentioned also states that it disappears before the rash fades. Cotting claims that the temperature is highest when the eruption first develops; Kassowitz, that it vanishes by the second or third day; Klaatsch, that it is slight, and lasts but one day.

Some writers, however, consider fever a much more prominent symptom. According to McLeod, it ranges from 100° to 105°; E. L. Fox says it is rather high for the first two days; Edwards reports it as often 103° to 104°; Paterson states that the temperature is high; and Cheadle reports an epidemic in which it reached 103° at the beginning of the eruption, and increased to 104° to 105° as this developed. These so numerous conflicting statements by different writers form but an additional proof of the variability of the temperature in rubella.

In the cases reported here the amount of catarrh and fever was usually found to be in direct proportion to the extent and intensity of the eruption. This rule seems to express the opinion of most writers. Yet the greatest elevation of temperature and the fullest development of the eruption, either generally or upon any one part of the body, were not necessarily attained at the same time. Emminghaus claims that they never come together; and Thomas, that they have no connection with each other, as is the case in measles. There were, too, a certain number of patients in which this rule did not hold good. In some of these there was considerable fever and but little rash; in others, a wide-spread eruption with complete apyrexia. The same exception was sometimes found in the relation between the catarrhal symptoms and the eruption. Reed, indeed, claims that the symptoms are not in proportion to the development of the rash.

The *pulse* and *respiration* in rubella are not often increased more than is in accord with the elevation of temperature. I have observed a pulse-rate of about 150 in two instances. Paterson and Cheadle speak of the pulse as rapid.

The condition of the *tongue* is a most important one for diagnostic purposes. I have never seen the "strawberry" or the "peeled" tongue in this disease. It was always either clean or covered with a thin, yellowish-white coating, through which the slightly enlarged papillæ near the tip sometimes projected.

This is the condition described by so great a majority of writers that discussion is almost precluded. It may safely be considered a characteristic of the disease. Yet it is but right to state that a different condition has sometimes been reported. Hemming agrees with Balfour and Tripe in describing the tongue as more or less dirty; then developing the "strawberry" appearance, and finally becoming smooth. Murchison says it may exactly resemble the tongue of scarlatina. Burnie makes the presence of the "strawberry" condition one of the diagnostic symptoms which distinguish rubella from measles. Alibert says the tongue is red and slimy. Tompkins reports a patient who had already had measles, developed rubella with a typical "strawberry" tongue, and later suffered from scarlatina. All such cases must be considered, at least, in the highest degree anomalous.

One of the most characteristic symptoms of rubella is the *enlargement of the lymphatic glands* behind the ear and back of the sterno-cleido-mastoid muscle. Maton in 1815 observed them, and remarked their importance. While describing the features which distinguish rubella from the roseola of Willan he says, "besides, tumors do not occur in roseola."

It is safe to say that this glandular enlargement is present in almost every case. Hardaway has not found it absent in a single instance. J. F. Meigs[1] looked upon the enlarged post-auricular gland as one of the most prominent diagnostic signs of rubella. Squire, Hardaway, and Thierfelder say it may often be detected before the rash becomes visible. The very constant occurrence of this symptom is further testified to by Gerhardt, Mettenheimer, Douglas, Earle, Emminghaus, Tonge-Smith, Edwards, Duhring, and many others.

Eustace Smith, however, only states that it is present in some epidemics; and Kassowitz discovered it in only one-third of his cases, but noticed that it was the last symptom to disappear. The presence of this glandular swelling, with its very early appearance and long continuance, has recently had even greater stress laid upon it by writers in the English journals. Glover, Jalland, and Strover report instances in which it even accompanied the stage of incubation; and Squire reiterates his former statement to this effect.

I have rarely failed to detect the enlargement of one or more glands. Though not perceptible on the first day in some cases, it became clearly so on the second. The tumefaction lasted a variable time, often continuing after the rash had quite disappeared.

I must state, however, that I have repeatedly detected a similar enlargement in measles, and believe it would be oftener found if oftener sought for.

The occasional occurrence of enlargement of the glands of other parts of the body is mentioned by Thomas, Klaatsch, Hardaway, Tonge-Smith, and Emminghaus. The latter writer even includes it among the prodromes. In the severer cases of those reported here, Dr. Musser frequently detected a tumefaction of the axillary and, especially, of the inguinal glands.

Œdema of the face accompanying the eruption is referred to by Douglas. It was present in a number of my cases.

An *odor* has been said by Heim to attend the eruption. He claims that it is the same as in scarlatina, while Squire writes that it often smells like measles. I have found no other reference to it.

Itching is sometimes an attendant on the rash. It is mentioned by the older writers, and by many of the more modern (Vogel, Thomas, Mettenheimer, Maton, Bourneville and Bricon, Hardaway, Edwards, Emminghaus, etc.). The general opinion is, that it is absent in the greater number of cases.

A peculiar *roughness of the skin*, giving a sensation to the hand much like that produced by *cutis anserina*, was noticed very frequently by Drs. Shoemaker and Musser and by myself. This not only accompanied the rash, but persisted, often, days after all redness had disappeared. I find very little attention called to this very common symptom, though Golson and a few others refer to it.

[1] Personal communication.

Nausea and vomiting are usually considered to be among the rarest of symptoms. Bourneville and Bricon have seen vomiting in but one case. Paterson and Aitken state that it sometimes occurs; Kingsley and Cheadle, that it is seen in severe cases. Parke and McLeod consider nausea and vomiting very rare; but J. L. Smith thinks them common. Edwards, too, mentions vomiting as frequent, and in five cases as almost uncontrollable. In a very few of the severest cases included in this report it was observed upon the first day of the eruption.

The *bowels* are regular or confined.

Desquamation.—As the red color of the eruption disappears, I have often seen spots of a faint brownish or yellowish color remaining, which in a short time vanished in their turn. This appearance has been observed by many writers. Cheadle, Thomas, and Edwards speak of a very delicate, fleeting yellow tinge. Kassowitz describes a marbling of the skin persisting for six to eight days after recovery. Rilliet and Barthez report delicate yellowish spots; Emminghaus, an indistinct cloudy pigmentation; and Stone, a staining of the face lasting two or three days.

There may or may not occur a slight branny desquamation, following almost immediately the disappearance of the eruption. It was present in a large number of the cases reported here. It has never been observed by Thomas, Steiner, Fleischmann, Brodie, McLeod, Wilson, Goodhart, Cuomo, or Bourneville and Bricon. Other writers whom I have consulted say, almost without exception, that it is slight, and always furfuraceous, but is often wanting. Aitken and Paterson state that the scales on the soles and palms are larger than elsewhere, but never so large as in scarlatina.

Desquamation is usually completed in from one to three days. Occasionally it lasts a longer time; and, according to Squire, may persist until the third week. Edwards has seen it continue twenty days. Scholl claims that he has seen it last until the fortieth or fiftieth day. Hemming, Paterson, Aitken, and Edwards describe it as beginning in the centre of a patch and extending toward the periphery. The latter also states that the buccal cavity takes part in the desquamation.

Complications and Sequelæ.—Those who (as Goodhart) have described the disease in its very lightest form state that there are none, and this is certainly true in the vast majority of cases. Other writers have reported very various morbid conditions attending or following rubella. The most common affections are those of the respiratory apparatus. Severe bronchitis and pneumonia are mentioned by Emminghaus, Cheadle, J. L. Smith, Earle, Parke, and Edwards. Ryle and Edwards each saw pleurisy once. Tonge-Smith describes a secondary sore throat, appearing on the third or fourth day, and accompanied by high fever and much swelling, but never by sloughing. Severe sore throat is also reported by Emminghaus among others. Eustace Smith makes the secondary throat affection a characteristic of rubella. A membranous deposit upon the tonsil is reported by Cheadle, and embarrassed and stridulous respiration by him and by Glaister. According to Parke and Slagle, croup was sometimes present, and the former says marked adenopathy in the cervical region and under the tongue occurred in a large number of cases. Diphtheria was observed by J. Lewis Smith. Mettenheimer reports nasopharyngeal catarrh, inflammation of the mucous membrane of the mouth, and permanent enlargement of the tonsils as sequelæ. The rare occurrence of albuminuria and the dropsy attending it is a disputed point. It is mentioned by Emminghaus; and Kingsley, Cheadle, Duckworth, and Reed each report 1 case. Hatfield found slight albuminuria in 2 cases; and Cuomo, in 3. Liveing says it is not infrequent; and Edwards, that it was present in thirty per cent. of his cases. Roberts claims that transient albuminuria is not uncommon, but that true renal disease is very rare.

On the other hand, Mettenheimer and Squire say it never occurs; Tonge-Smith has never seen it; and Hardaway writes, "it would be safe to say that such cases are entirely anomalous, if not, indeed, in some instances examples of mistaken diagnosis." With this statement the mass of observers will, I think, concur.

The occurrence of intestinal catarrh must be considered a most unusual complication. Vineyard says there is constipation, sometimes followed by severe diarrhœa; and McLeod, that diarrhœa is rare. Tompkins reports one case in which the bowels were loose; Balfour considers catarrh of the colon a common symptom. Gastro-intestinal irritation is mentioned by Emminghaus, and reported by Earle in 3 or 4 cases; but Edwards states it was present in forty per cent. of his. He also reports 10 cases of enteritis, and 2 of entero-colitis. In the description of an epidemic, almost as severe as that of Edwards, Cheadle considers the absence of intestinal catarrh characteristic of rubella, and as distinguishing it from measles. Cuomo found diarrhœa frequent in a series of cases which he himself calls in all respects very anomalous. The majority of writers make no mention of the state of the bowels, having evidently found nothing to note. Stomatitis is reported by Hatfield in 2 cases, and by Edwards in 4; aphthæ, by the latter and by Earle. Erysipelas was a sequel in several cases according to Alexander. One patient of J. L. Smith developed varicella. Hardaway has seen otorrhœa and ciliary blepharitis follow; and Cordell, typhoid fever, but hardly calls it a sequel. De Schweinitz has noted 2 cases of phlyctenular keratitis. Curtman saw abscesses form in different parts of the body; and Golson, in the submaxillary lymphatic glands. Rheumatism developed in a few of Earle's cases, in 2 of Edwards', and in 1 of Slagle's. Urticaria was observed by Slagle, Earle, and Cullingworth. Golson reports a feeling of numbness following desquamation, and claims that abolition of voluntary motion in the arms and legs sometimes occurs and lasts for several days. Slagle has observed a painful enlargement of the thyroid gland in 6 instances. Thierfelder describes an œdema of the face, and Emminghaus a similar condition of the legs as a sequel. Cheadle found earache often develop, as the rash subsided. Convulsions and delirium are reported by Aitken, Paterson, and others of the writers of that time.

Among the 150 cases reported here but few complications or sequelæ were seen. Pneumonia developed in 2 cases under my care—in the one upon the fourth day, and in the other on the seventh day, after the appearance of the rash. Urticaria complicated the disease in 1 case of Dr. Musser's, and icterus followed in another. In several cases which had very recently been vaccinated rubella seemed to run an unusually severe course. In 1 of the patients treated by Dr. Shoemaker diarrhœa occurred on the day before the rash developed, but ceased before the latter appeared.

None of the complications or sequelæ which have been described by writers are seen except with the greatest rarity.

Relapse.—Most writers do not mention the possibility of relapse, and I have found none dispute its rarity except Kingsley and Cuomo. The former says it occurs frequently, and the latter saw it in every one of the 90 anomalous cases which he reports. It was witnessed seven or eight days, on the average, after the beginning of the disease, and was ushered in by similar but less intensely severe prodromal symptoms. Emminghaus says relapse occurs but seldom, and takes place immediately after the disease is over, or after an interval of about two weeks. He saw it in 3 cases. Earle records it in 2 instances; Edwards, in an equal number—in one case on the fourth, in the other on the twentieth, day; Golson, in 1 case on the seventh day. Köstlin and Lindwurm have also reported cases. Three of the cases reported in this paper suffered relapse. These were

children under the care of Dr. Musser, and had all had rubella badly. In the first and second cases the rash reappeared, with a renewal of the catarrhal symptoms, three weeks after the onset of the disease, and in the third patient after an interval of eleven days.

Prognosis; Mortality; Treatment.—As a rule, rubella is a disease of no danger whatever. This is the opinion of by far the greater number of writers. Squire says, "Where a mortality is reported as high as three per cent. of those attacked, measles is present." Yet severe cases and epidemics do occur, and deaths, usually from the complications, do take place. A few of the purely uncomplicated cases reported here were sick for several weeks from the depressing effect of the disease itself. The older English writers, as Paterson, Copland, and Aitken, thought the prognosis must be guarded, and that death frequently occurred. Edwards reports seven deaths (4.25 per cent.), and Hatfield a mortality of nine per cent. I have also found fatal cases published by Alexander, Hemming, Slagle, Roberts, and Cuomo. In one case of Balfour's the child died of croup before the rash appeared. McLeod says the mortality is trifling. Several cases died in Toronto in an epidemic in 1882. Treatment, except hygienic, is rarely needed. A light diet should be given; confinement to bed enjoined for a few days, if there is fever, and to the house for a week or longer. All chilling of the body is to be avoided, and severe symptoms or complications treated as they develop.

Conclusions and Diagnosis.—The mystification which surrounds rubella, the confusion into which contradictory statements have plunged the subject, are, I think, explainable on the following grounds:

1. Rubella is liable to wide variation, and anomalous cases and epidemics occur, as in other specific febrile diseases.

2. As described by the older writers, it certainly differed greatly, if not totally, from the disease as it now exists.

3. There has been a disposition shown by many modern writers to describe their cases or epidemics as necessarily representing the typical form of the disease.

4. Errors in diagnosis are easily made, and descriptions of genuine cases are sometimes very faulty.

In order, then, to draw from the mass of published matter any conclusions, or to formulate any description of the disease which may be generally applicable, some accounts must be entirely ignored, and all reported cases carefully weighed and balanced. In considering, for example, the severe epidemic reported by Edwards, it must be remembered that an epidemic of measles was prevailing in the hospital at the same time. And it must be taken into consideration whether the opinion of Jacobi and of West may not perhaps be correct as expressed at the International Congress of 1881—viz., that rubella prevailing simultaneously with measles or scarlatina may be influenced by it, and may take on symptoms not belonging to itself. This is the view of Hatfield regarding the severest of his 110 cases. The cases reported by Cheadle were also very severe, and must be considered wholly anomalous; and Cuomo entertains this opinion of his own graver cases. On the other hand, Thomas, Squire, and some others describe rubella in its very mildest form, and it would be a mistake to suppose that it must always exhibit just such symptoms. The following condensed description of the disease is the result of an attempt to thus combine the careful study of the cases reported here with the analysis and comparison of the numerous published accounts consulted.

Rubella is an acute, specific, epidemic, and contagious febrile disorder, occurring but once in the same individual, and entirely independent of both measles and scarlatina. It is a disease of childhood, although adults and infants do not always escape. The incubation is of very variable length, lasting one to three weeks. Prodromes are usually absent or slight, continuing rarely more than twelve hours, and consist of malaise, drowsiness, slight catarrhal symptoms, slight sore throat, sometimes fever and enlargement of the glands, and occasionally nausea. The eruption is maculo-papular, pin-head to split-pea size, pale-rose, multiform, usually discrete, sometimes grouped as in measles, sometimes confluent as in scarlatina. It appears first on the face, and spreads rapidly to the body, persisting in all about three or four days. It either reaches its maximum successively on different parts, and fades from each rapidly, or it is at its height everywhere at once upon the second day. The symptoms of this stage are those of measles, but very much less severe, and perhaps entirely wanting, combined with more or less sore throat and enlargement of the glands at the back of the neck. The temperature is very variable—often not elevated, rarely exceeding 101°, often falling to normal on the second day, but frequently persisting a much longer time. Desquamation is absent, or slight and branny. Complications and sequelæ are rare. The prognosis is favorable, and treatment not often needed. Cases of a much graver type are sometimes seen, in which the symptoms are much exaggerated; and death may occur, usually from some complication.

Diagnosis.—The more important diagnostic points are the short duration and slight import of the prodromes, the absence or slight degree of the catarrhal symptoms, the slight degree of fever and its variability, the presence of more or less sore throat and of enlarged lymphatic glands at the back of the neck and behind the ears, and the occurrence of cases in epidemics. As already emphasized, it is frequently impossible to diagnose sporadic cases if at all abnormal. For convenience of reference, a table of well-recognized diagnostic symptoms distinguishing rubella from measles and from scarlatina is appended. This cannot be claimed to be complete, inflexible, or applicable to anomalous cases. In tabulating the symptoms of measles and scarlatina, the articles in Ziemssen's and Gerhardt's "Cyclopædias" and in Pepper's "System of Medicine" have been principally consulted.

Table for Differential Diagnosis.

Rubeola.	Rubella.	Scarlatina.
	Incubation.	
Fourteen days.	Very variable; one to three weeks.	One to seven days.
	Prodromal Symptoms.	
Usually last three days.	Absent, or seldom longer than twelve to twenty-four hours.	Last twenty-four hours or less.
Severe catarrhal symptoms of nose and eyes; considerable cough.	Catarrhal symptoms, if present, usually slight.	
Slight sore throat not uncommon.	Sore throat often attends.	Marked sore throat.
Vomiting occasionally.	Vomiting very rare.	Vomiting a frequent symptom.
Decided fever, with a characteristic temperature-curve.	Fever absent or slight.	High fever; rapid pulse; marked nervous symptoms.
	Eruption.	
First on the face.	First on the face.	First on the neck and chest.
Spreads gradually; maximum all over body by second or third day.	Spreads very rapidly; either fading from one part before in full bloom on another, or with universal maximum in twenty-four hours.	Spreads slowly; maximum reached by fourth day.
Lasts average of four days.	Lasts three to four days or less.	Usually lasts six to seven days or longer; sometimes much less.
Color deep red; often purplish.	Color usually pale rose-red.	Color intense red; dusky or livid in some cases.

Rubeola.	Rubella.	Scarlatina.
Papular; arranged in irregular or crescentic groupings.	More or less elevated; spots smaller than in measles; discrete or confluent; seldom arranged in groupings.	Minute red points; confluent in large patches or universally.
	Symptoms of Stage of Eruption.	
Severe catarrhal symptoms persist and increase; severe bronchitis common.	Slight catarrhal symptoms persist or may appear.	Coryza in bad cases.
Throat sometimes sore.	Slight sore throat nearly always present.	Sore throat a very marked and constant feature.
Glands sometimes enlarged as in rubella.	Glands behind ear and at back of neck almost always enlarged.	Glands below jaw often much enlarged.
Tongue coated; in bad cases dry and brown.	Tongue clean or with thin yellow coat; *never "strawberry" or "peeled."*	Tongue "strawberry," and later denuded.
Temperature 102–104°; ascends slowly; maximum with that of eruption.	Temperature variable; rarely over 101°; no constant connection of maxima of temperature and eruption; often normal by second day.	Temperature usually 104–105° from outset for three to four days.
	Pulse in proportion to fever.	Pulse very rapid.
Diarrhœa usual during eruption.	Almost never diarrhœa.	
Albuminuria not very common.	Albuminuria exceedingly rare.	Albuminuria a common occurrence.
	Desquamation.	
Branny.	Absent, or slight and branny.	In flakes or rolls.

States in which a Medical Examination is Required before One can Get a License to Practise.—A correspondent asks: "If a person is a graduate of a regular medical college in good standing and holds a diploma from the same—say the University Medical College of the City of New York—and is now in practice in Connecticut, but wishes to remove to another State, in how many States of the Union, and which are they, in which he can practise by merely exhibiting his diploma?" Thirty-three States now have medical practice laws. Most of these simply require the exhibition of a diploma from a reputable college. We have not the means of telling all the States that require an examination in addition. We believe, however, that Virginia, North Carolina, Alabama, and California require an examination in addition.

CEREBRO-SPINAL FEVER.

By JAMES J. LEVICK, M.D.,

PHILADELPHIA, PA.

With much satisfaction I have read the very able paper of Dr. J. Lewis Smith, printed in the The Record, May 14th, p. 542, and the interesting discussion which followed its reading before the Northwestern Medical and Surgical Society.

It so happened, early in my medical life, that unusual opportunities for the study of cerebro-spinal fever were afforded by the prevalence of this disease, in its epidemic form, in the winter of 1862-63. In May, 1866, as chairman of the committee on "spotted fever, so-called," I prepared and read, at the meeting of the American Medical Association, a paper on this subject, in which the history of this disease from its appearance in Europe, A.D. 1505, to the epidemic in America of 1863 is given.

In it especial attention is called to the sudden outburst of spotted fever in New England in 1806, to the essays of Gallup, North, and Wilson, and to the remarkably full and interesting report of the committee of the Massachusetts Medical Society appointed to investigate the nature of this disease, March 27, 1810.

So accurate are the descriptions given by these writers, nearly a century ago, that but little which is really new has since been added. To those of the profession now interested in the subject, I may, perhaps, without vanity —rather for what I have collected than what I have myself written, direct their attention to my report, which may be found in the "Transactions of the American Medical Association," vol. xvii., page 311 *et seq.*

Without doubt, during the last six months there has been, over a wide-spread extent of country, an unusual prevalence of cerebro-spinal fever. It has been so, as appears from Dr. Smith's paper, in New York and in Jersey City, and it certainly has been so in Philadelphia. Here it has shown itself, not so much in the great number of the persons affected as in the great fatality of those attacked by it. Here, too, as in all previous visitations, it has thrown its livery over other prevailing diseases, disguising their ordinary symptoms and rendering obscure their diagnosis.

Especially has this been the case with typhoid fever, where intense pain in the head and nape of the neck, unusual muscular soreness and hyperæsthesia of the skin, have preceded and masked the true typhoid-fever symptoms, which later have shown themselves.

With this disease in a community, as with epidemic catarrhal fever (influenza), to which I have long believed cerebro-spinal fever is closely allied, differing rather in degree than in nature, there will always be found an unusual number of persons suffering from languor, malaise, debility, and mental depression. Such has been the case here during the months of April and May to an extent rarely known at this season of the year.

Twenty years ago, of course, there was no mention made of the micro-organism of cerebro-spinal fever. Dr. Smith calls attention to the fact that the micrococcus of pus from the cerebral meninges and that of pus in croupous pneumonia are identical. In this connection, it is at least an interesting coincidence that in every epidemic of cerebro-spinal fever there have been numerous cases in which the force of the disease has been spent on the lungs rather than on the brain. Such, it is now agreed, was the character of that terrible epidemic known as *pneumonia typhoides*, which devastated New England in the early part of this century.

Dr. J. C. Warren, in the epidemic of spotted fever in 1810, found purulent deposits in the pleura, lungs, and pericardium. Dr. Gallup, 1807, says: "In spotted fever it is difficult to fix on any one particular organ as its place of constant habitation. As the eruption upon the surface is sometimes universal, so the affection of all the internal membranes is sometimes discoverable. It might be called *the mocking fever*, as it assumes the mask of most others." And yet, that it is an independent, primary disease there can be no doubt. Dr. Smith, in his paper, and others, in the discussion which followed, say that in all the cases noticed by them the eruption was absent. Such was not the case in four instances coming under my notice recently, in all of which it was well marked. Two of these cases occurred in the practice of Dr. Eagleton, of this city, and were seen by me in consultation, and by his permission are reported. They occurred in an old frame-building, almost the only one left in this part of the city, the occupant of which carried on shoemaking in the front room, while his family inhabited the other part of the house. There were no water-pipes inside the building, but an ordinary privy converted into a water-closet was immediately adjoining the house.

The family consisted of father, mother, and five children. February 11th, Henry, aged ten, previously in good health, was at school in the morning, but in the afternoon complained of headache, and had nausea and vomiting. During the night there was fever, with delirium and intense pain, referred to the epigastrium. Next morning, though unable to leave his bed, he seemed much better, and entertained his little friends in his room during the afternoon. In the morning he was seen by a physician, who regarded the case as one of peritonitis. Toward evening he became more and more delirious, and died after an illness of thirty-six hours. After death numerous petechiæ were found in various parts of the body.

Vinnie, aged eighteen, sister of this boy, was as well as usual until Saturday, March 4th, having been at a wake until after midnight. Early in the morning she complained of chilliness, with severe pain in the forehead, with nausea and vomiting, and was extremely weak. Dr. Eagleton first saw her at 3 P.M., and found her vomiting a greenish matter, with pain both in the front and back of her head, her pulse very feeble, but with no delirium. At 6 P.M. she became unconscious, pupils widely dilated, conjunctivæ injected, head retracted, and arms and chest dotted with petechiæ. She died at 8 P.M., after an illness of twelve hours.

James, aged seven, another brother, previously in good health, was taken ill on the evening of May 19th, with sick stomach, vomiting, severe pain both frontal and occipital, delirium, fever, marked retraction of the head; chest and arms dotted with petechiæ. In this case, too, the pupils were widely dilated and the conjunctivæ greatly injected. He died at 9 P.M., May 21st, within forty-eight hours of the seizure.

These cases were identical in their mode of attack, symptoms, course, and fatal termination with those seen by me in the epidemic of cerebro-spinal fever of 1862–63.

April 14, 1887, I was called by Dr. F. B. Hazel to see with him a little girl, thirteen years old, who, though previously in good health, was seized while walking on the street with sudden loss of power in her lower extremities; so much so that she would have fallen had she not been supported. She was carried to her home, suffering from pain in her knees and in the muscles of the trunk.

This was rapidly followed by pain in the head, upper part of the spine, with rigidity of the muscles of the neck, retraction of head, loss of power of deglutition, rapid failure of heart-power, and death. In this case no petechiæ were discovered, nor was there any great change of temperature, and the mind remained bright and clear until death, which occurred three days after the seizure.

May 24th, with Dr. Hazel, I saw a child, fifteen months old, who had been delicate, but with no family history of tubercle. The child had been ill for three days, lay in a partial stupor, with ptosis of the left eyelid and complete paralysis of that side. There were the usual symptoms of acute meningitis, and but for the prevalence of cerebro-spinal fever, the case might readily have been

regarded as such. Shortly before the child died one or two livid extravasations were seen behind the ear, and after death numerous petechiæ showed themselves.

This case corroborated the statement of Dr. Smith (p. 543), that cases of cerebro-spinal fever may be reported as infantile paralysis, meningitis, and the like. Other errors of diagnosis might readily be made, not the least unlikely of which would be the mistaking of it for acute rheumatic fever.

The cases reported furnish but little information as to treatment. In two of them the heart-failure was so rapid that stimulants, both internally and externally, were at once imperatively demanded. In another case, at the very beginning, quinine was administered, and when the spots showed themselves hypodermic injections of ergot were given.

In two cases calomel was given freely in the early stage of the disease. To the little girl, with pain in the knees and muscles, opium, in moderate doses, was given, but in no instance were large doses of opium thought to be safe, so feeble was the spark of life, almost from the first.

Where there are extensive petechial eruptions medicines avail but little. Almost the only case of recovery from this condition I have ever known was that of a little girl, six years old, whom, I confess, I treated very empirically, with small and frequently repeated doses of calomel, and who was kept for three days enveloped in hot blankets within which were bags of hot salt, frequently renewed day and night, a mode of treatment suggested by that practised by the New England people, who were in the habit of surrounding spotted-fever patients with billets of wood which had been boiled in a decoction of the leaves and boughs of the hemlock. The child recovered perfectly, with none of the terrible sequelæ which are so common after this fever.

Asiatic cholera is a disease which, very properly, has claimed the closest attention of the profession. Commissions have been appointed, and men have been sent, as it were, to the ends of the earth, to study its cause, nature, and prevention. And yet, happily, so rare is its visitation, that a whole generation may pass by without witnessing it. Cerebro-spinal fever, on the other hand, if it have not already become so, bids fair soon to be endemic among us, while its frequent appearance as an epidemic may well strike terror in a community. As in the cases reported in this paper, it enters a family and desolates the home. It strikes down its victim on the public street, or tears from the mother's embrace her helpless child.

Surely a pestilence thus walking in darkness, and a destruction thus wasting at noonday, should have thrown on its path all the light that science can give and all the restraints that an intelligent profession can supply.

1,200 Arch Street, May 29, 1887.

Rapid Staining of the Tubercle-Bacillus.—Dr. Gabbett writes to *The Lancet*, strongly recommending the following slight modification of Neelsen's method of staining the tubercle-bacillus in cover-glass preparations. The stain is made by dissolving 1 part of magenta in 100 of five per cent. watery solution of carbolic acid, and adding 10 of absolute alcohol. Heat this fluid over a spirit-lamp till steam rises freely. Float the preparation (made in the usual way), cover, and leave for two minutes. Then immerse in a solution of methylene blue in twenty-five per cent. sulphuric acid (made of a dark-blue color) for one minute, keeping the watch-glass in motion. Finally, rinse the cover-glass in distilled water, dry, and mount in balsam. The whole process occupies about five or six minutes. The only novelty in this method is the combination of the decolorizing fluid and contrast stain, which are used separately in Neelsen's method. The results are far better than those obtained by any of the other rapid methods; and Neelsen's carbolic solution of magenta is distinctly preferable to any of the preparations made with aniline.

IMPLANTATION OF TEETH—YOUNGER'S METHOD.[1]

By F. ABBOTT, M.D.,
New York.

The operation to which I have the pleasure of calling your attention for a few moments this evening, aside from its mechanical features, is very little understood, even by those who have performed it the greatest number of times. That teeth which have been for a long time out of the mouth, and, as supposed, entirely devoid of life, are inserted into artificial sockets made in the maxillary bones in the mouths of human beings, and there remain, become firm, useful, and to all appearances as good and healthy as the adjoining teeth in the same mouth, there can be no doubt.

Operations in the same direction, such as the transplanting of teeth, *i.e.*, the removal of a badly decayed tooth, or root, and the placing of a sound one, previously taken from the mouth of another person, into the socket, and there held by ligatures for a time, until union of the periosteum upon the root with the tissues of the socket has taken place, have been done with more or less success, occasionally, for some two hundred and fifty years, possibly for thousands of years even. However, the first published statement in reference to it, that I am aware of, is to be found in the work of Ambroise Paré, published in 1634. He says: "I heard it reported by a credible person, that he saw a lady of the prime nobility, who, instead of a rotten tooth she drew, made a sound tooth, drawn from one of her waiting-maids at the same time, to be substituted and inserted; which tooth in process of time, as it were taking root, grew so firm as that she could chaw upon it as well as upon any of the rest. But as I formerly said, I have this but by hearsay."

I say the operation of transplanting has occasionally been done. It probably would have been performed—and would be at the present time—more frequently, but for the fear many people have of being inoculated with some dread disease, should they have a tooth taken from another person's jaw and inserted in their own. I judge, however, that a hundred years ago people were less fearful of such a catastrophe. Judging from the every-day manner in which the operation is spoken of, it would seem to have been very common. I find in a small book entitled "A Practical Essay on the Human Teeth," by Paul Eurialius Jullion, Surgeon Dentist, published in London in 1781, in a list of "his accustomed charges," the following:

	£	s.	d.
Transplanting a living tooth.....	5	5	0
Ditto a death tooth	2	2	0

In the "Natural History of the Human Teeth," by John Hunter, 1778, may be found a description of this operation, as well as that of replantation. It is from this work that the idea of "implantation" was first suggested to Dr. Younger. Hunter then recommended that a tooth be replanted when taken out through mistake, or knocked out accidentally, immediately, if practicable; if not, he would replace it even after it had been out of the mouth twenty-four hours, or "at any time before the socket began to fill up." To sustain his opinion that a tooth would become firmly fixed in its socket again, even after having been out of the mouth so long a time, he gives his own experience in replanting, and an experiment in implanting a freshly extracted tooth into a cock's comb as follows:

"I took a sound tooth from a person's head, then made a pretty deep wound with a lancet into the thick part of a cock's comb, and pressed the fang of the tooth into this wound, and fastened it with thread passed through other parts of the comb. The cock was killed some months after, and I injected the head with a very minute injection; the comb was then taken off and put into a weak acid, and the tooth being softened by this

[1] Read before the Section in Surgery, N. Y. Academy of Medicine, May 9, 1887.

means, I slit the comb and tooth into two halves, in the long direction of the tooth. I found the vessels of the tooth well injected, and also observed that the external surface of the tooth adhered everywhere to the comb by vessels similar to the union of a tooth with the gum and sockets."

The replantation of teeth, *i.e.*, the replanting of teeth removed through mistake or by accident, and the removal of teeth for the purpose of enabling the operator more directly to treat chronic alveolar abscess, or difficult cases of pyarrhea alveolaris, and replacing them, has been practised by many dentists for a great number of years. Hunter speaks of replanting teeth removed through mistake or accident, as though it was at that time, and had been, a common practice. While the removal of teeth for the purpose of getting at and treating disease is a more modern operation, and, as a rule, anything but satisfactory in its results.

It was while reading the experience, recommendation, and experiment above quoted of Hunter that the question suggested itself to Dr. Younger, that, if a tooth would grow fast again in its own socket after it had been out of it twenty-four hours or more, and that a freshly extracted tooth would grow fast in an entirely foreign tissue such as a cock's comb, why would it not grow fast in an artificial socket made in the maxillary bone of a human being? Certainly the soil ought to be better suited to it than a cock's comb. After considerable reflection upon the subject he concluded to try it. This he did, I believe, first some three or four years ago, since which time he has done the operation some forty or fifty times (perhaps more), and, I believe, in the majority of cases, with marked success.

The operation is performed in the following manner: A tooth for the place is first selected, the pulp-chamber opened, and the pulp from that and the canal as perfectly removed as practicable, and the canal and drill-hole are filled; it is then placed into an antiseptic solution (bichloride of mercury, 1 to 2,000). A cross is then cut through the gum to the bone, at the point where the socket is to be made to receive the tooth. The corners of the gum thus made are slightly dissected from the bone, and a trephine the size required is then inserted through the opening in the gum, and driven with the dental engine to within about a fourth of an inch of the depth desired; the remainder of the socket, owing to its tapering shape, is finished with different-sized and shaped burrs and reamers. When, in the judgment of the operator, the socket is about the size and depth to receive the tooth, he tries it in; if the tooth fits as desired the operation is proceeded with; if not, the tooth is removed and the socket enlarged in this manner, cutting and fitting until the tooth stands in the socket in a correct position. The tooth is then removed and again placed into the antiseptic. The socket is now washed out thoroughly with the antiseptic, and the tooth placed in position. In some cases it is necessary to ligate it to adjoining teeth for a time; in others it is held as firmly as required by the impinging walls of the new socket. The gum over the tooth is then painted with equal parts of the saturated tincture of aconite root and the tincture of iodine. The pain attending the operation is caused chiefly by cutting through and dissecting up the gum, and the trying in of the tooth. This may readily be controlled by the application of a small quantity of muriate of cocaine crystals to the parts for a few minutes, before the cutting is done.

I may add that different kinds of instruments are used by different persons for making the socket, such as drills, spear-shaped burrs, etc., but those described are the kind Dr. Younger uses and prefers to any others.

The question which more particularly interests us all, in connection with the operation of implantation of teeth, is, does a union of the tissues of the bone and the periosteum upon the root of the tooth take place? So far it has been impossible to satisfactorily settle this question, as no one who has undergone the operation has felt disposed, after the lapse of sufficient time for the union to have taken place (if such be the case) to have the tooth removed, even for scientific investigation. I have known of two, however, which have been taken out, one after three days and the other after five days from the time they were inserted, and it was thought in each case that a partial union had taken place.

From the fact that many of the apparently successful cases of Dr. Younger and others have been done with teeth which have been out of the mouth three, four, six and in one of Dr. Younger's thirteen months, it would seem that it cannot be that any growing together of these tissues really occurs, but rather that the tooth is mechanically held in its new socket. I will now ask you, gentlemen, to examine a case which I have here, and as far as possible satisfy yourselves upon this point. The case is in the mouth of a colored man, Calvin Brooks. He resides in this city, is a hard-working, industrious man, but takes not the best care of his teeth.

Some four and a half years since he had the right central incisor of the upper jaw extracted. After going without a tooth for some time he had a plate inserted with a tooth upon it (this, I believe, was renewed subsequently), which he wore, with more or less discomfort, until October 5, 1886, when, at a clinic, a patient was wanted for Dr. Younger to operate upon. This man was requested to submit to it, which he did, and the operation was done as before described.

No tooth suitable for the place being at hand, one was obtained from the Colton Dental Association. When presented for insertion it was dry; so much so, that the enamel was as white as chalk, and the periosteum upon the root was apparently as lifeless as a bit of parchment. As near as could be ascertained, it had been extracted some three or four months previously.

In examining the case it will be observed that the tooth is even more firmly fixed in its new socket than the adjoining teeth, that the gum upon the labial surface and between the teeth presents a normally healthy appearance, while upon the palatal surface, on account of the removal of the amount of bone necessary for the reception of so large a root, it has slightly receded. Its irritated appearance at that point is in a measure due to a slight deposit of tartar upon the neck of the tooth. It will also be observed that a thickening of the anterior plate of bone over the tooth has taken place, an apparent reformation of the alveolar process.

This tooth was not ligated to adjoining teeth, but was placed in position and allowed to take care of itself.

The instruments I have here are Younger's, with an improvement by Dr. W. W. Walker, of this city, who kindly loaned them to me to exhibit this evening. The improvement consists in a slight tapering of the trephine upon the outside. This prevents binding of the instrument while it is being driven into the bone. The burrs and reamers I have been unable to obtain. In summing up the subject, it would seem that there are but two serious objections which can be offered to this operation; viz., the pain attending it and the danger of inoculation. As I have before stated, the former may be controlled, and it is believed that all danger of the latter is effectually removed by the use of antiseptics. This as yet, however, is an open question.

Tests for the Purity of Cocaine: 1. When heated upon platinum it must disappear without residue. 2. Solutions of cocaine must be of neutral reaction. 3. Sulphuric acid, when added, should not discolor its solution. 4 When to a solution of cocaine, 1 to 200 or 1 to 500, one drop of a two per cent. solution of potass. permanganate is added, the liquid should become red but remain clear. If the permanganate is added in drops beyond this point, a red precipitate of cocaine will fall, which will become brown on heating, but will give no odor of bitter almond.

SEPSIS AND ANTISEPSIS IN SUMMER DIARRHŒA.[1]

By SILAS ALLEN POTTER, A.M., M.D.,

ROXBURY, MASS.

WRITERS upon summer diarrhœa appear to be agreed that fermentation holds an intimate relation to the disease. Dr. H. C. Haven[2] says: "It will, I think, be universally admitted that, in its totality, summer diarrhœa of infants is a zymotic or fermentative disease." Maximilian Herz[3] states, in regard to cholera infantum: "It is pretty generally admitted that putrefaction of food, as Baginsky maintains, is an important cause of cholera infantum." J. Lewis Smith[4] writes, of infantile diarrhœa of summer: "Undoubtedly one of the most important causes is to be found in the very free exhalations arising from decomposing animal and vegetable matter during the heated term, and the disease is always most frequently met with in those localities where the accumulation of filth is the greatest."

It is the object of this paper to collect the more important facts about fermentation, and consider their relation to the disease in question.

The terms sepsis and antisepsis we wish to employ in a broad sense, to indicate, on the one hand, injurious effects resulting from micro-organisms; on the other, influences adverse to the life or activity of micro-organisms.

The alcoholic fermentation is produced chiefly by the yeast fungus, torula cerevisiæ; the lactic-acid fermentation, chiefly by the bacillus lactis; the butyric-acid fermentation, chiefly by the bacillus butyricus. Of these three processes it may be affirmed that the principal organism concerned in their production has been determined. This certainty has been reached by the isolation of the organism, the introduction of a pure cultivation into an appropriate sterilized medium, and the obtaining of the proper chemical decomposition.

Other fermentations, such as the acetic, ammoniacal, viscous, putrid, have not been studied with the accuracy which the later methods of research permit. Though due to bacterial action, it is impossible to designate a particular organism as their sole or chief cause. The micrococci found in putrefying material are yet undifferentiated, and the bacterium termo, believed by Cohn to be the essential cause of putrefaction, has already been proved to be a name covering more than a single variety of organism. It is not improbable that the same may be shown to be the case with the micrococcus ureæ, micrococcus aceti, and others.

However, it is not so much with the particular organism producing these various changes that we are now concerned, as with the grand fact that the cause of fermentation and putrefaction is vital. "Micro-organisms," writes Carl Fraenkel,[5] "are the producers of fermentation, and, what in the economy of nature is a still more important part to play, are the cause, and the only cause, of the putrefaction of organic substances."

When it was proved that it was the exclusion of bacteria from a wound that averted the traumatic infective diseases, a scientific basis was at once given to antiseptic surgery. If we believe that summer diarrhœa in a vast number of instances would not occur but for fermentation, then a recognition of the cause of fermentation is the initial step in our understanding of the disease.

It is not claimed that, in defining the chief morbid process, the ultimate cause of the disease has been demonstrated. It is well known that bacteria are constantly present in the digestive tract in health. It is even possible that they are useful there. Before reaching the ultimate cause, the question must still be answered, why these organisms, at one time subject to the control of the body, become at another productive of disease.

The action of fermentative organisms in causing diarrhœa is probably indirect, the more immediate agent being substances produced by the microbes through the decomposition of the fluids in and upon which they live.

According to Flügge,[1] the chief products of bacterial action are: Gases, as CO_2, H, CH_4, HS_2, NH_3; water; sulphur; volatile bodies, as trimethylamin, alcohol, formic acid, acetic acid, butyric acid; fixed acids, as lactic, malic, succinic, oxalic, tartaric; sulpho-acids, as taurin, amides of the fatty acids, especially leucin, alansin; bodies of the aromatic series, as tyrosin, phenol, cresol; reduction-products, as indol, hydroparacumaric acid; complex molecules, as carbohydrates, pepton, hydrolytic ferments; coloring matters, and poisonous alkaloids.

Of these substances two classes, some members of which at least are produced by the bacteria of fermentation, are interesting in the study of diarrhœa—the acids, and the poisonous alkaloids.

Acids can excite diarrhœa by immediate irritation of the mucous membrane of the bowel; the alkaloids indirectly, by a systemic effect. The simpler, less violent cases of diarrhœa can often be traced to the irritation of undigested food and the acid substances produced in its fermentation: the more sudden and violent cases seem often to call for the agency of a poison.

It was long ago noticed that serious illness oftentimes followed the eating of decomposing meat, fish, or cheese.

Kerner was the first to suspect that alkaloids were formed by the decomposition of albumen, and in 1820 called attention to the similarity between the poisoning by sausages and atropia.

Panum, in 1856, demonstrated that putrefying substances often contained poisons which, when injected into animals, caused death. That death was not due to the activity of bacteria in the body he showed by sterilizing the fluid before injection. He also proved that the inflammatory changes in the intestinal mucous membrane of animals poisoned with putrid material was not caused by the bacteria in the putrid fluid, but by chemical substances which retained their character even after boiling.

Selmi, of Bologna, gave to these alkaloids formed by the decomposition of proteids the name of ptomaines.

Necki, in 1876, first obtained ptomaines in a pure form and determined their chemical symbols.

Brieger, however, in 1885, produced the most important results which have been obtained in this branch of investigation. From putrefying meat Brieger isolated three alkaloids which he called neuridin ($C_5H_{14}N_2$), neurin ($C_5H_{13}NO$), and cholin ($C_5H_{15}NO_2$). From putrefying fish he obtained muscarin ($C_6H_{15}NO_3$), gadanin ($C_7H_{17}NO_2$), and a base allied to ethylin-diamin ($C_2H_4(NH_2)_2H_3O$). From decomposing gelatine he separated neuridin, muscarin, and dimethylamin. Of these, neuridin is most constantly present in commencing putrefaction. The existence of the others seemed to depend in some degree upon the kind of material undergoing decomposition. From putrefying human bodies Brieger obtained several substances of alkaloidal character—neurin, cholin, cadaverin ($C_5H_{16}N_2$), putrescin ($C_4H_{12}N_2$), saprin ($C_5H_{16}N_2$), trimethylamin ($(CH_3)_3N$), dimethylamin, triethylamin, mydelain, and a substance of undetermined composition.

The physiological action of these various compounds differs widely. Some, as neuridin, cadaverin, putrescin, and saprin, are either harmless or must be injected in very large dose to produce toxic symptoms; others are violent poisons. Of the latter, there are five which bear an important relation to the study of diarrhœa—neurin, muscarin, cholin, mydelain, and the substance whose composition was not determined. The action of the first three is essentially identical, the most important symp-

toms produced by a fatal dose being salivation, vomiting and diarrhœa, dyspnœa, paralysis, and death. Mydelain, when injected into guinea-pigs, even in the very minute quantity of three-fortieths of a grain, causes profuse secretion from the eyes, nose, mouth, and intestine, dilated pupils, exophthalmos, an increase of temperature, paralysis, fibrillary twitching of muscles, dyspnœa, and death. In cats the symptoms did not essentially differ, diarrhœa being prominent as before. The substance of undetermined composition, when injected into rabbits and guinea-pigs, caused excessive peristalsis and exhausting diarrhœa. In general it may be said that most of the alkaloids which have been obtained by the decomposition of albumen have a tendency to produce diarrhœa.

It does not follow, because ptomaines capable of exciting diarrhœa are formed outside the living human body, that they are formed likewise within. There are, however, strong reasons for believing that such may be the case.

Substances capable of putrefaction exist in the digestive canal. Of such the most common in children is milk, but no article of food can be assumed to be absent in either adults or children. In many cases, besides food, there will be mucus, serous exudation from inflammatory surfaces, blood, pus, or sloughs.

The micro-organisms which accompany putrefaction, and are believed to be its cause, are present in the digestive tract. Johnston, in the examination of the vomitus of seventeen breast-fed infants affected with summer diarrhœa, found invariably micrococci and what is known as the bacterium termo. In diarrhœal fæces he discovered innumerable bacteria, especially of the varieties mentioned. Since bacteria exist in the digestive tract in health, it must be supposed that while digestion is being normally performed the conditions are unfavorable to the multiplication of organisms. Spallanzani found that when substances in which putrefaction had begun were introduced into the living stomach the process was checked. We may suppose that, in order to initiate fermentative changes, organisms enter the body in uncontrollable numbers, or that the digestive function is in whole or in part suspended.

The products of fermentation are found. With the sour vomitus and the acrid or foul stools of summer diarrhœa all are familiar. The search for alkaloids in diarrhœal excrement has probably not been made; but such have been found in healthy fæces, and that freshly voided fæces are poisonous has been proved by Bouchard. It is probable that the amount of poisonous alkaloids formed in disease is greater than in health, and also that their amount and the conditions under which they are produced render them less subject to the eliminative action of the body.

What is known of ptomaines throws light upon certain obscure conditions arising in summer diarrhœa. There are cases of cholera infantum in which violent symptoms are followed by a speedy death, and yet no appearances adequate to explain the result are revealed by the autopsy. There are also cases of diarrhœa, some acute, others subacute, which a few hours before death show, with the condition called hydrencephaloid, a rise of temperature. The nervous symptoms may be referred to exhaustion. It is difficult, however, to explain the increase of temperature by either exhaustion or a fresh inflammatory process begun in those last few hours of life. It seems more reasonable to believe that in both this case and the former a septicæmia has been induced by the products of putrefaction, either absorbed from the digestive canal or generated in the exhausted tissues of the body.

It is easily remarked that in no case of summer diarrhœa do the symptoms correspond completely with those following the administration of a given ptomaine to an animal. Of this an explanation is offered by the fact that it is impossible for a single ptomaine to exist alone in the digestive canal, since both the albuminoids and organisms present are various. Moreover, different ptomaines, though they may have similar, may possess antagonistic powers, so that the effect of any one may be modified or even neutralized. It is therefore impossible to predict with exactness, from experiments outside the human body, what the action of the alkaloids of putrefaction will be when formed within the human body.

Many of the expedients which have been found useful in the treatment of summer diarrhœa possess some element unfavorable to the growth of micro-organisms.

The removal of a child from the city to the country or sea-shore is, in high degree, an antiseptic measure. Investigation into the bacterial contents of the air and earth show that micro-organisms diminish in number as we rise from the surface of the earth, as we penetrate beneath it, and as we go out upon the sea. They are absent in the high Alps, absent or very scarce in the lower strata of the soil, and absent, so far as investigation has gone, in the sea air a thousand miles from land. In the Rue de Rivoli, on the contrary, in the centre of Paris, there are ten times as many microbes in the air as at the fortifications without the city, and at Montsouris Observatory the north winds blowing over Paris bring many more microbes than the south winds from the country. The most impure come from the hills of Villette and Belleville, populous quarters in which also are cemeteries and slaughter-houses. In other words, where there is decomposing organic material there are bacteria, and the greater the amount of the one the larger the number of the other. What is true of air is true in a higher degree of water. Condensed aqueous vapor has been found to contain nine hundred bacteria to the litre; sewer-water from Clichy, eighty millions. It is where human beings are crowded together in large numbers that the greatest consumption and excretion of organic matter takes place. It is here, therefore, that the widest necessity exists for those retrograde processes which it is the peculiar province of fermentative organisms to affect. We are justified, therefore, in looking upon filth and sewage as the grand culture-medium of fermentative organisms, the special soil in which flourishes the cause of summer diarrhœa. Removal from this contaminated environment would therefore be demanded by theory and is approved by practice. It is readily seen, however, that the advantage which the country naturally possesses over the city can be nullified for any particular place by unhygienic local conditions. The insufficient drainage of a country town, the cess-pool under the window of an isolated farm-house, create the same danger which is encountered in the midst of dense population. It is, in all cases, the proximity of decomposing organic material which is to be avoided, its absence which is to be desired.

The transferrence of a child from the bottle to the breast is an antiseptic measure. Milk as it comes from the breast is free from organisms, and human milk, even when allowed to stand exposed to the air, will, according to Baginsky, resist fermentation a number of hours longer than cow's milk.

The heating or boiling of milk is an antiseptic procedure. The ancients used to quench flints in milk to render it more serviceable in the treatment of diarrhœa. Household observation has taught that boiled milk keeps. The more exact studies of the laboratory have shown that an exposure to the temperature of boiling water for a few seconds in a moist medium will kill all bacteria, while a continuance of this temperature, under the same condition, for fifteen to thirty minutes will destroy their spores. A fermentescible fluid, thus sterilized, will remain unchanged until bacteria are once again admitted. To completely sterilize milk is hardly compatible with the conditions of a nursery. An approach to this can, however, be effected by boiling milk in the same bottle from which it is to be afterward nursed. The bottle should be stoppered with cotton before boiling, and the stopper removed only when the milk is required for use. Ex-

periment has shown that milk thus prepared will keep sweet in a warm room for twenty-four hours, while unboiled milk, standing in a pitcher by its side, will in that time have become sour and coagulated. To thus defer for a few hours the capability of milk to ferment may be all that is required in the treatment of some of the minor cases of vomiting and diarrhœa in infants.

All means for emptying the digestive tract, either by withholding food or by giving evacuants, have an antiseptic value. On the one hand, micro-organisms are deprived of the material necessary for their growth; on the other, both organisms and their products are swept away. Evacuants have from a remote period been held in favor in the treatment of diarrhœa. The Greek physicians used mild laxatives to remove the "peccant humors" from the system, and Piso, who introduced the use of ipecac for its emetic and cathartic effect in the fluxes, described it, in his extravagant language, as "a sacred anchor and most exquisite gift of nature."

Various drugs have been used to produce disinfection of the digestive tract. Of these, the most powerful is corrosive sublimate, and they range in strength from this down to borax or salicylate of sodium. To determine the comparative value of these in the treatment of summer diarrhœa does not at present seem possible. It would appear that the value of a particular drug does not depend upon the precise grade of its antiseptic power. A milder antiseptic may, all things considered, be more valuable than a stronger one. Nor does it seem probable that absolute antisepsis of the digestive tract is either possible or necessary. The fact that the processes of digestion in health are conducted in the presence of bacteria leads us to think that nature controls the micro-organisms. It is probable that she can do something for herself in most cases of disease. The part of medicine is so to modify unfavorable conditions as to restore to nature the control which she had previously lost.

The main positions advocated in this study of summer diarrhœa are:

1. That micro-organisms bear an important causal relation to a large proportion of cases of summer diarrhœa.

2. That antisepsis of the digestive tract is an essential element in the treatment of the disease.

3. That in antisepsis must be included not only the use of drugs, but also the establishment of all conditions known to be unfavorable to the life and activity of micro-organisms.

4. That in order to a more scientific use of antisepsis we require more adequate information as to what organisms are concerned in the production of fermentation, their life-history, and the conditions favorable and unfavorable to their growth.

Hospital Managers and Visiting Physicians.—Philadelphia has been recently disturbed by two hospital difficulties. The managers of the Homœopathic Hospital for Children found that the members of the medical staff were making use of mother tinctures, cathartics, alcoholic beverages, and other preparations which do not come under the homœopathic roof. Accordingly the managers notified the offenders that this must be stopped. The members of the staff denied the right of the managers to dictate to them. The managers retorted that the hospital was incorporated for the purpose of ascertaining the true value of homœopathy in the treatment of children's diseases, and that the physicians in charge must confine themselves to strictly homœopathic measures or resign. Whereupon the staff unanimously submitted their resignations, which were accepted. It is not stated whether their places were promptly filled by other physicians. But in the other instance, a highly esteemed surgeon was suddenly removed from the visiting staff, and his successor was promptly and easily found. The gentleman who succeeds, however, seems to have incurred the disapprobation of the profession of the city.

Clinical Department.

THE USE OF INDIGO AS AN EMMENAGOGUE.

Dr. S. T. Yount, of La Fayette, Ind., in a paper read before the Tippecanoe County Medical Society, recommends very highly the employment of indigo as an emmenagogue. He writes: "It is perfectly safe, thoroughly reliable, and painless in its action. It is insoluble in water or alcohol, but readily dissolves in strong sulphuric acid. This so changes its character that it is then readily soluble in water without changing its color.

"It is odorless and tasteless, and may be given in doses of ʒ j. to ʒ ss. The great difficulty is the nausea and vomiting which the crude drug produces when given in very large doses. There are three varieties of the crude drug: Bengal, Turkey, and Chinese.

"The Bengal is richest in coloring matter, containing about fifty per cent., and inasmuch as the virtue resides in the coloring matter, the best effects are obtained from this variety. As an emmenagogue it has been used in my practice about a year and a half. My attention was first directed to it on one occasion when I was called to remove a retained placenta in a case of abortion at the third month. Naturally inquiring what had been taken to produce the abortion, I was told that the lady had taken indigo in teaspoonful doses three times a day, that she had taken it several times, and always with a most satisfactory result to her.

"She informed me at the time that it always produced great nausea and watery discharges from the bowels. Acting on the suggestion offered by this case, I tried it in many and various cases. In one case, where a young lady, aged eighteen, had missed for thirteen months, the menses returned after taking the crude indigo for two weeks; but the disgust and nausea produced by the bulky powder rendered her unable to continue it longer, and she menstruated three more months; then they stopped again. After using the remedy for eight or nine months in this crude state, I set about to find some way of condensing it, or rendering it less bulky, for it is the bulk of the dose, not the remedy, that disturbs the stomach and disgusts the patient. About a month later Mr. O. G. Zerse, an apothecary of La Fayette, turned over to me a concentrated extract, as he called it, five grains of the extract equalling twenty-six grains of the crude drug. I have since then used it in forty-eight cases of amenorrhœa, of all kinds and causes, with but three failures, and a colleague has used it in six cases without any failure. To test its effect I have given the remedy in the amenorrhœa of phthisis, and have always had a definite result, namely, the appearance of the menses, the menses stopping again when the remedy was stopped. The effects with the crude drug and the concentrated preparation are identical, except that the nausea does not occur when the extract is used. The menses come on painlessly and very suddenly. There is no warning given. In thirty cases the effects occurred about two days after the last dose, the menses coming on without any warning, gushing out and running often to flow. The hemorrhage in none of the cases was dangerous or alarming. During the administration of the drug the os uteri becomes soft and patulous, admitting the end of index-finger. There is often a serous discharge from the vagina. The urine becomes of a brownish-green color and offensive odor. The stools are of a bluish color. The passages are watery and offensive.

"To summarize, indigo is an emmenagogue of decided value in any case. It should not be given to pregnant women. It should not be given where there is an irritable stomach. It should not be given in cases where there is a history of a previous pelvic inflammation. It should not be given in cases where there is marked cerebral anæmia. It may be given in doses of ʒ j. to ʒ ss., two or three times a day, of the crude drug, or in five-grain

doses of the concentrated extract. The powder of the crude should be given mixed with a little subnitrate of bismuth, and the patient should drink a little whiskey afterward. In cases where given continuously for a long period, give tr. gentian comp. after each dose. Give the concentrated extract in capsules mixed with extract of gentian and subnitrate of bismuth."

A NOVEL REMEDY FOR ASTHMA.

Dr. Samuel E. James, of Frankfort, Ky., reports the case of a man who had been a sufferer for years from paroxysms of asthma, and had tried various remedies with but little relief and no permanent good, and was in a condition to adopt anything that would promise a good result. One of his fellow-workmen told him that if he would take a few bird-shot every day for a while he would get relief from his trouble, and without further questioning he purchased one half-pint (about four pounds) of No. 8 bird-shot, and proceeded to take a teaspoonful three times a day. He continued to do this for three weeks before he found it necessary to send for a physician, though he had had colic almost every day since he began this novel treatment. Noticing the retracted condition of his abdomen and the offensive nature of his breath, Dr. James examined his gums, and discovered a well-marked blue line in both the upper and the lower jaw. Upon being asked if he had been where he could have contracted lead-poisoning, the patient confessed to having taken the shot. Constipation had existed almost from the time he began this treatment, though he had had an operation every two or three days. Careful examination showed that there was no peritonitis, and that the vermiform appendix had failed to imprison any of the shot. The first indication seemed to be to remove the cause of the trouble, and this was accomplished in part by the use of active purgatives supplemented by injections. The result of the first experiment was the removal of about one pound of the shot. The patient was then given iodide of potash and an anodyne, and allowed to rest a day or two, when the cathartics and injections were resumed and an additional pound of shot removed. The bowels were kept open, and the discharges examined carefully, but no more shot were passed, and the patient continued to improve under iodide of potash, and at the end of three weeks had entirely recovered from the lead-poisoning. Dr. James adds: "The case is of interest as showing to what great abuse the alimentary canal can be subjected and still suffer no permanent lesion. The vermiform appendix seemed to enjoy a particular immunity from danger. Iodide of potash was a prompt and efficient remedy in removing the lead from the system, as was proven by repeated examinations of the urine. The blue line was marked, as the patient was unaccustomed to the use of a tooth-brush or tooth-pick. The appetite was not materially interfered with, and, aside from the pain, the patient suffered very little damage. His breathing was free and easy, and no paroxysms of asthma occurred while the lead was being eliminated, though the disease asserted itself after he had recovered from the lead-poisoning. The relaxation of the system from pain and shock probably kept the asthma in abeyance."

The Cure for Doctors' Quarrels.—The *Detroit Lancet* says the most quarrelsome doctors have one common characteristic, as a rule, viz., lack of a generous, broad culture. A doctor having such a culture will regard his time and strength altogether too precious to waste in any personal controversy. For the cure of doctors' quarrels, a four years' literary and scientific study and a four years' medical college and hospital training is advised. Thus doctors would learn the manners of gentlemen and of professional gentlemen.

Progress of Medical Science.

Hæmospermatism.—Dr. Harrington reports the following cases in the *Boston Medical and Surgical Journal:* In January, 1885, a single man, aged twenty-five, a teacher, of good physique and of excellent habits, came for advice because of a slight enlargement of the epididymis of the right side. It caused slight pain after long standing or walking. The patient had never had gonorrhœa. The immediate cause of this epididymitis seemed to have been a long cold walk with insufficient clothing. Cold applications and a suspensory bandage soon brought relief to his trouble. It transpired, during the course of the questioning, that there occasionally occurred a nocturnal emission which was reddish in color, and that the red color was also sometimes seen after straining at stool, and on one occasion after a cold seabath. There was no complaint of a frequent occurrence of these stained discharges, but they had caused the patient some anxiety. About seven years ago the patient first noticed this discoloration of the semen. There occurred intervals during which there was no staining, and at no time were the losses frequent, occurring on the average once a month. Nothing about the patient or his condition suggested spermatorrhœa. After the meatus had been snipped, a No. 29 French sound was passed with ease into the bladder, and caused no pain. There was no sensitiveness in the region of the prostate. Rectal examination showed no enlargement or tenderness of the prostate nor of the seminal vesicles. There was no pain on passage of urine or of semen, nor did movements of the bowels cause any distress. The patient had been accustomed to horseback exercise, but it never caused him any distress. He was requested to bring any specimens which it was possible to save. During the course of several months the following specimens were obtained: Two pieces of cotton cloth stained a reddish-brown, cut from the night-clothes, and a few drops of the fluid which were passed while straining at stool. This fluid showed microscopically numerous spermatozoa; a few red blood-corpuscles; a few granular nuclei; granules. It certainly deserved the name of a bloody seminal fluid. The seminal fluid may be discolored in several ways. An admixture of pus changes its color from gray to white or cream color. An admixture of blood may change the color to a bright red, an orange, a light brown, a dark brown, or a dark red. A dark-blue color is occasionally seen, but its origin is not clearly understood. The origin of the blood is generally believed to be in the seminal vesicles. An admixture may take place with blood from an inflamed urethra, but such a case would not be one of true hæmospermatism. There are several causes for the appearance of the blood. Vibert says that slight capillary hemorrhages in the vesiculæ seminales are of frequent occurrence among the continent and among old men. The cause is here an over-distention and irritation of the vesicles. Many authors (Lallemand, Ricord, Velpeau, Fournier, Gosselin, etc.) speak of bloody seminal fluid occurring after gonorrhœa. An extension of the inflammation to the seminal vesicles is a rare occurrence. Such inflammation is usually unilateral, affecting but one of the vesicles. By the rectum a hard or fluctuating mass can be felt, having the location and the general contour of the vesicle, but larger in size. There is pain on pressure and a constant dull pain, which is increased by defecation, by micturition, by coitus, and emission. Some authors claim that the blood comes from the epididymis or from the testicle, but it seems to be proven that the seminal vesicles are the usual source. A third cause, generally recognized by all writers upon this subject, is excessive coitus or masturbation. That such excess should lead to congestion and irritation is not surprising. The character of the patient and his statements justify the belief

that the cause of the blood in this case is over-distention of the vesicles. It may be possible that the discharge occurring at times after straining at stool, due probably to distention of the vesicles and to weakness of the ejaculatory duct, may have resulted from horseback exercise.

The Effect of Retained Membranes on the Puerperal State.—Dr. Fischer, of Professor Slavianski's clinic, has published the result of a number of observations made for the purpose of testing the commonly received view that portions of membrane retained in the uterus after the expulsion of the placenta are liable to produce serious consequences—as hemorrhage, and especially the so-called auto-infection or septicæmia—and that, therefore, it is of the utmost importance that they should be removed by the hand or by intra-uterine injections. This view is supported by the authority of Winckel, Dohrn, Ahlfeld, and others; while Olshausen, Credé, Weiss, and Landau consider that there is little harm in the retention of even considerable portions of the chorion. Dr. Fischer's observations extended over 682 labors, in each of which he carefully examined the afterbirth. In 42 of these cases (*i.e.*, 6.2 per cent.) a portion of the chorion was retained. Credé's method of manipulating the fundus uteri gave the best results regarding the percentage of retention. In primiparæ retention was nearly twice as frequent as in multiparæ, the percentage being 9.1 and 4.9 respectively. Some effect appeared to be exerted by the time at which the rupture of the amnion took place, which, when either too early or too late, seemed to predispose to retention. Premature deliveries also were rather more frequently followed by retention than those at term. As a rule, the retained chorion came away in the course of from four to six days, generally in several small portions, sometimes, however, in fragments of considerable size, and in one case, where three-fourths of the chorion had been retained, it was passed entire on the fifth day without having caused either hemorrhage or sepsis. Among the 42 cases hemorrhage occurred only four times, and was always easily arrested either by hot irrigation or by ergot and manipulation of the uterus. When, however, we learn that out of the 42 cases manual extraction of the fœtus was required seven times, and that a considerable loss of blood occurred during the third stage eleven times, 4 cases of slight post-partum hemorrhage does not appear at all excessive. With regard to pyrexia, in 20 cases, or 47.6 per cent., there was none; in 12, or 28.6 per cent., the thermometer, which was always used thrice a day, once registered a rise above normal; and in 10, or 24.8 per cent., there was more or less pyrexia. In order to compare these with cases in general, Dr. Fischer gives the results of similar observations made on all the cases he has attended for the last two years. These show that there was no pyrexia in fifty-eight per cent., that the temperature was only once above normal in 17.6 per cent., and that there was pyrexia in 24.4 per cent.; so that the ratio of appreciable pyrexia was about the same in the cases in which retention occurred as in ordinary cases. A slight amount of endometritis occurred in 3 out of the 42 cases. Dr. Fischer concludes from his observations that there is no ground for supposing that retention of fragments of membrane gives rise to "auto-infection," and considers that the commonly received view is fraught with danger, inasmuch as it tempts the accoucheur, when sepsis occurs, to throw the blame, not on himself, as he ought to do, but on some fancied auto-infective process, and thus probably prevents his being as particular as he should be in employing antiseptic methods in the management of the labors he has to attend.—*The Lancet.*

Kéfir.—Professor Lépine, of the faculty of Lyons, speaks of the therapeutic value of this substance in different affections of the stomach, for which he had lately given it to quite a number of patients. He makes no pretensions of its being a medicament, but calls it an aliment, for, like the koumiss, it is only fermented milk. Kéfir has the advantage of being more agreeable in its taste than koumiss. For hundreds of years the Tartars who live in the Northern Caucasian mountains have prepared a drink, which they call kéfir, gypy, kapyr, etc., by adding to cow's milk a kind of mushroom that is found in those high regions near the snow-line. This *champignon* is found in the form of irregular, compact, elastic seeds, varying in size, whose surface is rough and wrinkled, something like the tops of cauliflower. In the dried state they are yellowish, break easily, and look a little like cartilage. They contain two bacilli, one of which is like the bayonet-shaped bacillus found in spontaneously fermented milk; the other one has a little spore at each of its ends, and has been called *Dispora Caucasica* by Kern, of Moscow. To prepare kéfir, the grains are first of all to be swollen up by putting them into warm water for five or six hours; then throw them into milk after carefully washing them, and this milk is to be renewed several times (two or three) a day. After a few days they will have become active and ready to use for making the kéfir drink, which is done as follows: Take a tablespoonful of the fermenting seeds to each pint of fresh milk, and keep the mixture at a temperature of 64.5–66.0° F., shaking it every hour. The next day the mixture will be found in a mass, when it should be filtered through muslin, to get rid of the grain and all the impurities that may be in it. It should then be bottled, and the bottles must not be filled quite full, as it will go on fermenting for some time in them; they should be well corked, and shaken from time to time. In twenty-four hours more it is ready for use, unless it is desired to have a kéfir richer in alcohol, when it should be left for two or three days longer. After four days the drink becomes too acid to use. Well prepared, it should be a thickish, cream-colored, frothy liquid. It is richer than koumiss in albumenoids, less alcoholic, and not so acid. As regards its use, the Russian doctors find its indication in all the anæmic states, where it is not a specific, but it is a good tonic aliment. In chronic anæmia a half-gramme of lactate of iron is added to each bottle. It has been found of great benefit in all the diseases of the digestive tube where there is atony. Dr. Lépine used it in ulcer of the stomach, and found his patients liked it better than milk, and that their gastric difficulties were relieved by it. Other patients, suffering with dilatation of the stomach and catarrh of the same organ, were improved. It was sometimes used alternately with good milk, when it was noticed that those who could not tolerate milk could use the kéfir with great advantage to them. It has been proposed lately to use some other ferment in place of the kéfir mushroom; but, so far as known, experiments have been without success. It may be asked, Why not be satisfied with pure milk? There are a number of answers to this which will occur to all who advise milk; then there is the motive that induced man to transform grape-juice into wine—in a word, to introduce art into the preparation of his aliments.—*Paris Cor. of Philadelphia Medical Times.*

The Futility of the Superheated Steam Process for Disinfecting Rags.—Dr. S. H. Durgin, Chairman of the Board of Health of Boston, Mass., reports, from his experience with this method, that the moist heat passing from the centre to the surface of a bale of rags encounters knots or bunches of rags varying in degrees of density and of resistance to the penetration of heat; that while the temperature of the principal part of the bale is raised to a degree far above what is required for disinfection, other parts of the bale are found to be wholly unaffected by the heat; that anthrax bacilli having been killed and metals melted at 240° F. within bales of rags subjected to this process, are facts not inconsistent with the experiences here given, and do not prove the disinfection of the whole bale.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, July 9, 1887.

ALBUMINURIA IN HEALTHY PERSONS.

THE fact that albumen sometimes exists in the urine of healthy persons is well known, but it is generally believed, and in our opinion on good grounds, that such normal albuminuria is extremely rare, or produced only by peculiar dietetic conditions. Professor Grainger Stewart, however, now comes forward, and as the result of an analysis of the urine of four hundred and seven healthy persons, claims that one-third of all healthy people are albuminuric. One can hardly credit such a statement, although Professor Stewart's reputation as a careful observer makes his conclusions deserving of much attention. The tests used by him were cold nitric acid and picric acid. Of 205 soldiers, 77, *i.e.*, 37.56 per cent., had albumen. Of 74 civilians, 10.8 per cent. had albumen. Of 40 pauper children in one of the city poor-houses, 17.5 per cent. had albumen, and of 40 adult paupers of or about sixty years of age, 67.5 had albumen. Further investigations were instituted with a view to ascertaining the effect of diet. Thus it was found that, of soldiers, while 15.6 per cent. showed albumen before breakfast, the percentage was raised to 40.6 per cent. after breakfast. Of old men, 37.5 per cent. showed albumen before breakfast, while the percentage was raised to 67.5 after. Of children, 12.5 per cent. had albumen before breakfast, while the percentage was raised to 17.5 after.

Professor Stewart also (*Medical Press*) draws attention to the effect of exercise and exertion. Thus, of a party of soldiers before taking exercise, 29 per cent. had albuminuria, and on their returning from an eight miles' march the percentage was lowered to 19. Again, of a party of soldiers, 15.6 per cent. had albuminuria before breakfast, 40.6 per cent. after breakfast, and 28.1 per cent. after a march of eight miles. Professor Grainger Stewart thinks the following conclusions may be fairly drawn from his own and similar investigations: That there is no sufficient proof that albumen is normally discharged from the human kidneys. That albumen is much more common among presumably healthy people than was formerly supposed, tests having demonstrated its presence in nearly one-third of the population. That the frequency of albuminuria increases as life advances. That it is more common among those whose occupations involve arduous bodily exertion than among those who lead easy lives. That albumen frequently follows the taking of food, especially of breakfast, which more than any other meal increases the amount of albuminuria. That moderate muscular effort rather diminishes than increases albuminuria. That it is often induced by violent and prolonged exertion. That cold bathing produces or increases it in some individuals. That the existence of albuminuria is not of itself a sufficient cause for the rejection of a proposal for life insurance, a conclusion which is of vital importance to insurers, and to companies which have hitherto been in the habit of declining lives on this ground.

THE CONDITION OF THE CROWN PRINCE OF GERMANY —A CABLEGRAM FROM DR. MACKENZIE TO THE MEDICAL RECORD.

DR. MORELL MACKENZIE, of London, cables to THE MEDICAL RECORD the results of his third operation upon the throat of the Crown Prince of Germany. The entire growth has now been removed by the laryngeal forceps, and the parts beneath are in an apparently healthy condition. Dr. Mackenzie says: "Professor Virchow has examined the specimen and reports that its tissue showed nowhere any alveolar structure, or evidence of emigration of epithelial masses.

"The structure consisted of slender connective tissue, which contained only on its surface enlarged elements, partly undergoing proliferation, but the latter assumed nowhere the character of an independent focal formation."

So far, then, as the microscopical examination is concerned, the disease appears to be essentially of a non-malignant character.

The disposition toward limited cell-proliferation may be caused by active inflammatory processes in tissues peculiarly exposed to irritation, but from any other point of view the outlook is not as promising as it might be. Everything in the way of prognosis must now depend upon the fact whether or not there is to be any recurrence of the growth. If the latter obtains, with an increased disposition toward cell-multiplication, the chances for ultimate recovery will be on the wrong side. At present, however, we have reason to hope for the best, and shall await any future developments in the case with becoming interest.

THE TREATMENT OF OBESITY BY A REDUCED MILK-DIET.

VARIOUS are the methods which have been proposed for the relief of those suffering from an excessive deposit of fat in the tissues, and numerous are the cures which have been reported by the authors of these several methods, but yet fat people exist, and, indeed, judging merely from every-day observation, their numbers would seem to be increasing steadily. One reason why the treatment of the affection by any of the plans ordinarily adopted is so often ineffectual undoubtedly is because it is extremely difficult to induce patients to follow out conscientiously the regimen imposed upon them. It is such a trial to many people to deny themselves the pleasures of the table, and it is so easy to "treat resolution" occasionally, that the rules of diet laid down by the medical adviser are constantly being broken. But experience has shown that the more simple are the rules and the stricter, the more likely are they to be obeyed to the letter.

It is for this reason that a plan recently put in practice

by Dr. Le Menant des Chesnais (*Concours Médical*, May 14, 1887) appears to be worthy of notice. It is certainly simple enough, for it is nothing but starvation; and if the results obtained in two cases may be regarded as an index of what may be expected in others, the method might even prove serviceable in certain carefully selected cases.

The author's plan is to withdraw all food and drink absolutely, only milk in very small amount, to subdue the sensations of hunger and thirst, being allowed. Each time that the patient feels either hungry or thirsty he takes half a small coffee-cupful of milk. This is said to be sufficient to quiet the sensation for a time, and soon the patient becomes able to get along on less than a quart of milk in the twenty-four hours. The only disagreeable effect observed in the cases in which the author tried this plan was an obstinate constipation, which, however, was relieved by the administration of mild laxatives. In each case the treatment was continued for a period of five weeks, and in that time the first patient lost about twenty-two pounds, and the second sixteen.

Of course, great care would be necessary in the selection of cases suitable for such severe treatment as this, for it might readily be productive of serious injury. The treatment should be adopted while the troubles experienced are only functional, and before any organic lesions have arisen. The author suggests that the influence of small quantities of milk in obtunding the sensations of hunger and thirst may be due, in part at least, to the anæsthetic action of lactic acid, said by Germain Sée to be quite marked.

THE RELATION OF URIC-ACID EXCRETION TO HEADACHE.

Headache is a disorder to which physicians are perhaps even more prone than the majority of their patients, and one would suppose that they would be particularly interested in the subject. But it is not often that the matter receives very exhaustive treatment in medical writings, and we believe that the monograph of Dr. W. H. Day, published some years ago, is the latest which has appeared on the subject.

At a recent meeting of the Royal Medical and Chirurgical Society of London, Dr. Alexander Haig presented a paper on headache, which contained some interesting suggestions. Considering that headache has frequently some clinical relationship to gout, the author had examined the urine with a view of deciding the question. A headache was experimentally produced on himself by adopting a diet of meat and cheese. The urine excreted during the headache was kept separate from that excreted before and after. There appeared to be retention of uric acid before the headache, excessive excretion during the headache, and diminished excretion after the headache. Taking the three periods, however, and comparing the urines, there was no absolute excess of uric acid passed. The temporary excess during the headache was balanced by the diminution before and after. There was little change in the amount of urea passed during a headache, but the relation of the uric acid to the urea was greatly altered. When, after excessive exercise, there was a large excretion of urea and uric acid (though in their normal relation), headache was not far off; and if from any cause the uric-acid excretion fluctuated, headache would be present during its excess and absent during its diminution.

This fluctuation in the uric acid excreted did not affect the urea, and it was merely temporary and transient; it has also been proved that urates may accumulate while the kidneys are quite sound. Dr. Haig suggested that diminished alkalescence of the blood best explained all this. Gout, he thought, might consist in a diminished power of forming ammonia to neutralize acids, resulting in a permanent diminution of the alkalescence of the blood. A dose of acid, either from without or formed internally, might cause temporary retention of uric acid and so lead to headache.

Probably, however, as the author suggested, retention does not explain everything, as in his case the excess during the headache appeared to exceed the previous retention. There may be temporary excessive formation as well; hence the good effect of sodium salicylate, which lessens the formation of uric acid. The beneficial effects on this form of headache of a good meal, vegetarian diet, and alkalies were severally due to a temporary increase in the alkalescence of the blood.

THE DIAGNOSTIC VALUE OF EPISTAXIS.

Nosebleed occurs with greatest frequency in childhood, from the age of six or seven years up to puberty, and after that time becomes more rare. Boys seem to be affected more often than girls, a fact for which no satisfactory explanation has been offered, unless, perhaps, greater exposure to traumatism can be invoked. After puberty, however, the periodical loss of blood at the catamenia may secure a certain immunity in the case of women. Epistaxis occurring in childhood is more frequently idiopathic, while in adult life and old age it is usually symptomatic of some abnormal condition, leaving out of consideration traumatism, although even this is more efficient as a cause in childhood than it is in later life.

Since nosebleed is so often, in adults, only a symptom of some other condition, it not infrequently possesses considerable diagnostic and prognostic value, and we propose to consider, briefly, the phenomenon in its semeiological relation to various diseases, reserving for another occasion the discussion of its value in prognosis.

Obstinate and long-continued hemorrhage from the nose, coming on after a fall or a severe blow on the head, points, with considerable definiteness, to fracture of the base of the skull, involving the wall of the superior nasal fossæ. This diagnosis is rendered almost absolutely certain if the fluid escaping from the nostrils becomes watery and light-colored, from gradual admixture with cerebro-spinal fluid. The mistake must not be made, however, of jumping to a conclusion that a fracture exists, simply because epistaxis is present, for hemorrhage may be induced by the concussion, while the bones at the base of the skull remain intact. The bleeding in such a case is usually neither profuse nor of long duration.

Repeated attacks of nosebleed without apparent cause, especially if obstinate hemorrhages from other parts arise on slight provocation, would suggest the possibility of hæmatophilia, and should lead the physician to inquire

carefully into the family history of the patient, and more particularly into that of the male members of the family on the maternal side. Frequent hemorrhages may, however, be due to the presence of a small ulcer in the nasal mucous membrane, and the precaution of examining the nares in such cases should never be omitted.

The occurrence of epistaxis is often a sign of considerable diagnostic importance in typhoid fever. In measles, also, it is not uncommon at the beginning of the disease, while it occurs but seldom in scarlet fever and in rubella. It is common in anæmia and chlorosis, in malaria, and in various cachexiæ. Nosebleed may also point to disease of the vascular system. Abnormal thinness of the walls of the capillaries, atheroma, and the changes due to syphilis or alcoholism are the principal alterations observed.

At the meeting of the Academy of Medicine of Paris, held on April 26th, M. Verneuil read an interesting communication on the influence which certain diseases of the liver may have in the production of epistaxis, in which he claimed that nosebleed was often an indication of hepatic disorder, supporting his assertions by a recital of the curative effects of blisters applied to the right hypochondrium. This is not a new observation, for Galen speaks of the value of cupping over the hepatic region in arresting nosebleed, but it is a point that is not insisted upon as much as it perhaps deserves. Martineau, in his article on epistaxis, in Jaccoud's "Dictionnaire de Médecine," regards the occurrence of nosebleed as a symptom of great value in cases of doubtful hepatic disorder, and he agrees with Monneret that epistaxis always occurs at some period during the course of the disease of the liver, of whatever sort it may be. This is, perhaps, rather too sweeping an assertion; but, nevertheless, intercurrent attacks of hemorrhage from the nose are of remarkable frequency in diseases of the liver, and should be taken into account in the diagnosis of obscure cases. We may say, therefore, that, if ascites be present and its cause be not apparent, the supervention of attacks of nosebleed would lend very strong probability to the assumption that the serous effusion was due to obstructed portal circulation from liver disease. In cases of epistaxis occurring as a consequence of obstruction in visceral disease, the blood is not infrequently of a venous hue. This may also be of some service from a diagnostic point of view.

SHOULD DOCTORS DISPENSE MEDICINES?—THE DRUGGISTS' SIDE OF THE CASE.

We have received a letter from a correspondent who has been a druggist for fifteen years, but who is now, as he states, practising medicine. He thinks the views of our previous contributors plausible, but suggests that they forget that to be a druggist requires five years of hard labor and study.

"And what of it," he adds, "if the druggist does sometimes give something for diarrhœa or cramps? It is usually as good as what the doctor gives. I really think that the whole trouble lies in this — namely, the doctor looks upon the druggist as his slave, whom he can command at will, yet when he (the doctor) writes a prescription which no one can read, or is 'faulty,' he is all smiles and bows if his attention is called to the fact. I, for myself, think pharmacy and practice of medicine two distinctly different branches. It would be much better for the doctor to treat the druggist more humanely, and it will prove more to the interest of both parties."

Finally, our correspondent adds, truly, that this question has been up before, and he thinks that the pharmaceutical societies should have a word to say, and should perhaps try to enforce the law that compels persons who dispense medicines to have a license.

There is no danger that druggists will be driven out of the field by dispensary doctors. Middle-men must exist. The art of pharmacy is a necessary one. But everything may be abused, and it is very proper that certain lines of drugs, which the physician can easily use should be kept, prescribed, and dispensed from the office.

THE PRECEPTOR AND ILLITERATE STUDENTS.

Physicians who take into their offices illiterate students, and who help such persons into the medical profession, do a serious harm, and are responsible for much of the cry about overcrowding and a lowered tone of professional morals.

The Erie County Medical Society of this State has tried to prevent this practice of indiscriminately manufacturing medical students, by adopting a by-law compelling all members to take no students who have not passed a satisfactory examination before the Board of Censors. The by-law, however, has not been enforced, and recently the county society took action upon the matter and

"*Resolved*, That the Board of Censors is hereby directed to report at the next annual meeting, and at every subsequent regular meeting of the society, the name of any member, known to the censors, who shall, during the time, have admitted to his office as a student of medicine any applicant, without having received of him the necessary certificate of the Board of Censors, as provided for by Section 5, Article VI., of our By-laws."

ATHLETICS AND THE TYPICAL MAN.

Dr. D. A. Sargent makes a plea for a new gospel of athletics in *Scribner's Magazine* for July. Taking for his subject "The Physical Proportions of the Typical Man," the writer shows the evils of the present tendency to specialism in athletics, and advocates such a system of exercise as will be adapted to bring into development the weaker parts of one's anatomy. The object of athletics and of gymnastic exercise should be, he says, not extraordinary excellence in some particular line, nor the pleasure of battling and winning in athletic contests, but the bringing of the physical man into full and harmonious development. If an individual, though strong elsewhere, is weak in the back and thin in the legs, let his aim in athletics be to overcome this.

Dr. Sargent's idea is that of a Puritanism revived and applied to the body. Exercise is not for the gratification of contracting naturally strong arms in hurling the ball or wielding the bat; it is for the overcoming of defects. It is not for indulging the strong, but for strengthening the weak.

Dr. Sargent believes that he furnishes a solid founda-

tion for his gospel in the fact that he has by careful measurements of ten thousand persons established the normal proportions of the typical man. His article had been advertised in an almost quackish way, which led one to think the author would give to the world these proportions; but this he does not do, and therefore they cannot be criticised. It seems, however, that he has got them by averaging his series of ten thousand measurements. Such a method might be open to criticism, since the measurements do not apparently allow for race differences, and would be entirely different for ten thousand Englishmen, Frenchmen, Italians, and Americans.

We are left to infer that this "typical man" is the average of ten thousand young men in and about Boston. If he can show that his type represents the person in whom the muscles, the bones, and the viscera are arranged and disposed to the greatest possible advantage for accomplishing physical work and discharging their special functions, then only is his claim justified.

The gospel of physical harmony also needs this demonstration for its support, viz.: That the healthy, typically proportioned man lives longer, more fully, and more happily, than the healthy man with an extra-strong biceps, to whom cricket, and ball, and tennis are a perpetual joy.

We still incline to think that the cultivation of some enjoyable athletic specialty by which a man, though overdeveloping some part, yet keeps his system in excellent health, will be the stimulus for most athletic work.

Yet Dr. Sargent has done great service in furnishing a specific and worthy aim for those who have no inclination for a special exercise or sport. And his criticism of the abuses of modern athleticism deserves most serious consideration.

THE CITY LUNATIC ASYLUMS.

One may easily believe that there has been a great deal of elaborate lying in the testimony given regarding the management of the city lunatic asylums. No doubt this management is far enough from what it should be. But it is the easiest thing possible to find discharged patients and drunken ex-employés who will magnify accidents into routine customs and distort measures of necessary discipline into acts of tyranny and cruelty. Our city asylums are conducted as well as the average municipal institution. The serious defect, perhaps, in the present management is the iron-clad and almost penal discipline that is established. The close connection of the management with politics is another source of injury. Our city lunatic asylums are thereby cut off from the general current of medical work and thought. There could be no more important or easily accomplished measure of reform than the establishment, in connection with the asylum, of pathological laboratories, of visiting physicians and pathologists, with perfectly definite powers and duties.

RECENT CONTRIBUTIONS TO GASTRIC PATHOLOGY.

We have, on several occasions, called attention to the zeal with which French physicians have been pursuing the study of gastric disorders, and particularly of the stress they are laying upon dilatation of the stomach and toxic dyspepsia.

German observers have been following up the subject of abnormalities in the gastric secretion, more particularly that of the stomach acids. The *Berliner Medicinischer Wochenschrift*, the *British Medical Journal*, and the London *Medical Record* have furnished some interesting reviews and analyses of this German work. One of the points of great practical interest is that first made by Van der Welden, viz., that in cancer of the pylorus free hydrochloric acid is not secreted in the stomach. Several observers have given their support to this view. American physicians who have tried to put it to a test have, so far as we can learn, come to the conclusion that the methods of detecting HCl are too untrustworthy to make the method of value.

The presence of free acid in the stomach is ordinarily determined by adding to the suspected fluid a saturated alcoholic solution of tropæolin. This turns to a deep brownish-red with free acids, and to a light yellow with acid salts. To determine whether the free acid is lactic or hydrochloric, a weak solution of methyl-violet is used, which turns to an intense blue with free HCl. The presence of lactic acid is determined by adding a mixture of carbolic acid and ferric chloride, diluted with water to an amethyst-blue tint. This turns to a greenish yellow with lactic acid.

Cahn and Mering, in contending against the trustworthiness of these tests, says (*Deutsches Arch. für Klin. Med.*, xxxix., p. 233) that not only neutral chloride solutions, but magnesia-mixture, may produce a blue with this test; so may certain neutralized fluids from the stomach; also dissolved peptones, as before mentioned; amido-acids, and, in a less degree, mucin. They also state that lactic and fatty acids are not formed when a meat diet is given, but only free HCl (*Zeitschr. für Klin. Med.*, Bd. xii., H. 1, 2), whereas Ewald insists that lactates are formed as usual, while he agrees that the fatty acids are absent in such diet. The above authors also find that free HCl is not absent in cancer of the stomach.

Dr. P. Zeiwfl tries in another way to establish a method of assisting in the diagnosis of gastric cancer. This has already been described in these columns.

He ascertains the time of absorption of iodide of potassium (three grains), by testing either the saliva or urine. Its presence is usually to be shown within from eight and a half to seventeen minutes. A longer time than twenty minutes would accordingly indicate either cancer or simple dilatation of the stomach, and the latter diagnosis can be excluded by the sound or by gaseous distention.

Jaworski and Glusinsky have made some experiments, chiefly remarkable for the absurd conclusions to which they are led by them. They claim that the stomach is not a chemical, but only a mechanical digestive organ. Dr. Jaworski, and, more especially, Dr. Riegel (*Zeitsch. f. Klin. Med.*, 1886, xi., H. 1) have written elaborately upon the subject of "hypersecretio acida," and Riegel would apparently make the increased or diminished secretion of hydrochloric acid the centre of a large part of gastric pathology. He used Leube's method of examining the contents of the stomach a certain time after a meal; chemical tests were also instituted to determine the power and strength of pepsine, and the amount and kind of acidity. He reports four cases of typical "hyperse-

cretio acida," characterized by slow digestion, gaseous distention, pyrosis, and thirst.

Riegel distinguishes four groups of gastric disorders in which acidity is abnormal:

1. There is normal acidity (possibly, however, with severe derangement).

2. Free HCl and peptic power have quite disappeared.

3. Free HCl is present, but organic acids preponderate.

4. The peptic secretion is increased.

In cancer no free HCl was found, and no pepsine, but Riegel differs from Ewald in ascribing the absence of free HCl to its neutralization by the cancerous juices. Each author has observed a case of duodenal cancer also with loss of HCl.

Jaworski has just written again on the subject of hyperacidity (*München Klin. Wochenschr.*, Nos. 7, 8). This symptom, he insists, accompanies all disorders of the stomach, acute and chronic; but, if the condition persists long, the HCl becomes much lessened, and may entirely disappear. In other words, the "acid catarrh" may pass on to chronic "mucous catarrh," with entire derangement of function. This may occur from various causes, which are placed under two heads, namely, (*a*) spontaneous; (*b*) the use of alkaline drinks. Among the spontaneous causes of diminution, or even cessation, of HCl are the following: (1) Gastric ulcer with hemorrhage. The latter is preceded by great excess of HCl (and Riegel classes it under "hypersecretio acida"), which at last leads up to, and is temporarily relieved by, hemorrhage; but in some cases HCl ultimately ceases to be formed. (2) Dilatation. (3) The prolonged use of alcohol or other irritants (*Wien. Med. Wochenschr.*, No. 49, 1886). (4) Old age has a great predisposing influence (*ib.*, No. 50). The causes due to the persistent use of alkaline drinks embrace the prolonged use of Carlsbad and similar mineral waters, alkalies generally, and even borax.

Charcot on the Late Professor Vulpian.—"From the beginning of his career Vulpian divided his activity between the laboratory and the wards of the hospital. He was early led to understand that, without the assistance of experimentation, simple observation is often lacking in power; while, on the contrary, experimental data, at least so far as concerns human pathology, remains almost always without legitimate application when it is not constantly submitted to clinical control. The great characteristic of Vulpian's scientific life is this, that intimate union of the physician and the experimenter. Vulpian can be characterized by one word: he was the man of duty. Never was he seen to hesitate before a task which he had undertaken to perform. When he felt himself becoming feeble he resigned as physician to the Hôtel-Dieu, and gave up his private practice. Vulpian was a great and good heart, a family man ready to sacrifice all for his own, a master adored by his pupils, a firm and devoted friend."

There are now over seven hundred medical journals published in the different parts of the world, and the number is steadily increasing.

News of the Week.

The Death of the late Dr. Wilson Fox has rendered necessary the appointment of a successor to him in the Holme Professorship of Clinical Medicine at University College, and the appointment has just been filled by the election of Dr. Sydney Ringer, F.R.S., to the chair. At the same institution also, Mr. Victor Horsley has been appointed Professor of Pathology in place of Dr. Bastian, resigned.

Discussion over the Crown Prince's Case.—The *Medical Press* calls attention to the peculiar discussion which has been going on in the *British Medical Journal* over the Crown Prince's illness. The *Journal* led off with an article intimating that the laryngeal growth might though now benign, become malignant under the irritation inseparable from the use of the forceps. Mr. Butlin then contributes his views. "He is generous enough," says *The Press*, "to admit that Professor Virchow has had some experience of microscopical research—an admission for which Dr. Virchow will doubtless be duly grateful—but seems to think that the diagnosis of benignity was arrived at after too casual an examination, the fragment being, in Mr. Butlin's opinion, too small for proper observation. He concludes his perfidious letter by the recommendation to refrain from any expressions of triumph until we are in a position to know 'that Dr. Mackenzie has really well upheld the credit of English medicine abroad.' A more unkind, uncharitable, and unprofessional remark it would be difficult to imagine. The same journal contains a letter of an unconscionable length from Dr. Semon, who doubtless feels very slighted at not having been called upon to share the responsibility. After formally challenging the correctness of the idea that benign growths may develop into one of a malignant nature, he proceeds to admit that they may do so if a 'constitution tendency to malignant disease exists.' He goes even further, and admits that irritation may favor the morbid process. Another authority, Mr. Lennox Browne, has taken the trouble to show Dr. Semon that this opinion has all along been held by the most competent to judge, even if, from the nature of the question, it has not been mathematically demonstrated to be a fact."

The Late Dr. E. Darwin Hudson, Jr.—At a meeting of the Practitioners' Society of New York, held June 3, 1887, the following resolutions were authorized regarding the death of the late Dr. E. Darwin Hudson, Jr.:

Resolved, That in the death of Dr. Hudson the Practitioners' Society has lost a member who was endeared to all by his attractive personal qualities, and who added honor to the Society by his scientific work and his distinguished professional attainments.

Resolved, That the Practitioners' Society extend to the family of the deceased its earnest sympathy for them in their bereavement, and assure them that the members share in the deep sense of personal loss which Dr. Hudson's death has occasioned.

George F. Shrady.
V. G. Gibney.
C. L. Dana.

The Appointment of Dr. Joseph D. Bryant as Health Commissioner has caused general satisfaction. Dr. Bryant has had experience in sanitary administration, and he is a gentleman likely to show both wisdom and independence of action in his relations with the Board.

The Provident Dispensary Movement in England has at least not failed. There are now 88 such institutions with a membership of 293,720. Of these members 166,000 were treated on 700,000 occasions by 171 doctors who received an average of about 7½d. a visit.

Physicians Have the Right of Way.—The chief of police of Chicago has issued an order giving the vehicles of physicians precedence at bridges, along with the mail and patrol wagons, ambulances, and fire-apparatus.

The Report of the English Commission on M. Pasteur's Prophylactic will contain experimental and other evidence accumulated by the committee, strongly supporting both the theoretical views of M. Pasteur and their practical application. Mr. Victor Horsley, F.R.S., the secretary of the commission, has succeeded in rendering several dogs absolutely refractory to the virus of rabies in any form.

The National Medical Congress of Italy was held at Rome, beginning June 1st. Over three hundred physicians were present, and Signor Crispi, the Minister of the Interior, and other government officials attended the opening ceremonies. Signor Crispi gave an eloquent address on the work of the late Dr. Bertani, a man whose career should be familiar to all who love their profession. Dr. Bertani abandoned a brilliant academic and civic career to minister to the wounded soldiers of Garibaldi's army, and, after their common goal was won, devoted himself heart and soul to a department of medicine comparatively unfamiliar to him—public health—that he might render physically and morally sound and strong the national life he had helped to unify.

Dr. James E. Pilcher, U.S.A.—The degree of Ph.D. was conferred upon James E. Pilcher, U. S. Army, by the Illinois Wesleyan University at its last commencement.

Professor Erichsen, who is by marriage connected with the royal family of Germany, has recently been made a peer.

Small Medical Schools and Hospitals.—Mr. Hardy, in his prize essay on "The London Hospitals and the Jubilee," reproaches the smaller medical schools with being a source of expense quite out of proportion to their services, and he is evidently a partisan of the fusion of these smaller schools with their larger rivals. Such a course, it is clear, would be as advantageous to the cause of medical teaching as it would be, from a financial point of view, to the hospitals, and sooner or later the question will have to be seriously considered.

Homœopathic Troubles.—A Russian homœopathist recently delivered a public discourse on homœopathy before a mixed audience, and tendered the receipts, amounting to $200, to the Medical Students' Benevolent Fund. The committee declined the money, on the ground that it was the fruit of an ignorant and impudent attack on medical science. The Visiting Physicians to the London Infirmary for Consumption have all resigned, because the Governors have voted that homœopaths may be allowed on the staff.

Reviews and Notices of Books.

Short Contributions to Aural Surgery. By William B. Dalby. Pp. 78. London: J. & A. Churchill. 1887.

The Diseases of the Ear and their Treatment. By Arthur Hartmann. Translated from the third German edition by James Erskine. 42 illustrations. Pp. 283. New York: G. P. Putnam's Sons. 1887.

A Clinical Manual of the Diseases of the Ear. By Laurance Turnbull. Second revised edition. Numerous illustrations. Pp. 567. Philadelphia: J. B. Lippincott. 1887.

There has been great activity of late in the field of otological literature, including, of course, the entire upper air-tract. Among the numerous contributions are the three works under review. This may truly be regarded as the golden age of medical book-making; and though but little original matter of value can be found in the greater number, the time expended in running over them is not entirely misspent.

The little work of Sir William which heads our list comprises a series of eleven very cleverly written articles on "Accidents to the Ear," "Fatal Cases of Disease of the Middle Ear," "On the Loss of Hearing Power, without Perceptible Local Change," and the like. These have appeared in *The Lancet* during the past ten years. The spurs of Sir William were by no means won by his literary efforts, nor are these papers, indeed, offered as scientific essays. They serve the better purpose of adding to a reputation already obtained among the British gentry, and even with royalty itself, since its defective hearing organs have been inspected through the knightly aural speculum of our author.

The numerous works appearing of late on the ear and the adjacent region, the throat, may be taken as an indication of the interest felt in this department of medicine by the medical profession. The three works above mentioned are only a portion of what has been recently published.

The work of Dr. Hartmann is somewhat of an epitome of otological literature, especially of the modern German, with which he is familiar from a long experience in reviewing-work. The arrangement of matter is very neat and convenient, though the scope is not so broad as the title would indicate. But inasmuch as a number of recent treatises, written specially for students and practitioners, are now accessible to English readers, this is a matter of small consequence. It will, however, be read with interest by specialists.

Dr. Turnbull's second edition has increased in size by the natural process of accretion. It is doubtless not so easy to curtail the prosaical length of cases and therapeutical advice, or uninteresting citations from other writers, as to apply the pruning knife. In this work of nearly six hundred pages we find eight pages devoted to introductory generalities. There are twenty-one chapters, and an appendix of thirty-seven pages. The author has no faculty for the orderly arrangement of matter or of selecting what is valuable, and it is but faint praise to say that the present is some improvement on the first edition.

Opening the book at random, the reviewer was struck with the make-up of a table on page 56, which gives a classified list of six hundred cases treated by the author during three years, 1868–69–70. Thirteen deaths among six hundred cases is not perhaps a larger mortality than could be expected under the circumstances, but the causes of death must arrest the attention of all: Thus, 2 died of "otitis interna, pur. perf. (chronic);" 1 of "catarrh aur., media, acute perf.;" 4 of "otitis media, inflam. mastoid process;" 2 of "otitis media, chronic,

with caries;" 1 of "otitis media syphilitica;" and 3 of "periostitis, with abscess (cerebral)."

The neglect to observe the most ordinary care in the matter of nomenclature is truly remarkable, and a further inspection of the work leads one to believe that much carelessness of this kind exists throughout.

Turning to the appendix, we find it stated that the author has derived great advantage from the instillation of cocaine in operations on the ear; as in . . . "incisions, scraping, torsion, evulsion, écrasement, etc., in the tympanic cavity, when the drumhead is perforated, or in ulcers of the ear-canal and the auricle." We believe it has not been the general experience that cocaine deadens pain when applied to the diseased structures referred to, and we are sure otologists would feel greatly obliged to Dr. Turnbull for a more particular description of the methods by means of which these much-desired results were obtained. He seems also to have been particularly fortunate in curing persistent cases of chronic purulent inflammation of the middle ear by the use of a solution of peroxide of hydrogen introduced "by means of a spray." The author is to be commended for introducing in this connection a description of Sexton's operation of excision of the ossicles for the cure of these cases; though the difficulties to be surmounted in the performance of this operation, not to say danger when attempted by unskilful hands, have prevented him from adopting it himself. Yet, with characteristic justice, observed throughout, Dr. Turnbull manifests a spirit of fairness in bringing forward this as well as other advances in the field of otology.

The Surgeon's Pocket-book. An Essay on the best Treatment of the Wounded in War; especially adapted for the Public Medical Services. By Surgeon-Major J. H. Porter, late Ninety-seventh Regiment; late Assistant Professor of Military Surgery, Army Medical School, Netley. Third edition. Revised and Edited by Brigade-Surgeon C. H. Y. Godwin, Medical Staff; Assistant Professor of Military Surgery, Army Medical School, Netley; late Medical Officer of the Royal Arsenal, Woolwich. Philadelphia: P. Blakiston, Son & Co. 1887.

The first edition of this book was based upon an essay which the author wrote in competition for the prize, offered by the Empress of Germany, for the best essay on the "Practical Treatment of the Wounded in War," and to which a prize was awarded. The second edition contained numerous additions based upon the published experience of other army surgeons in different countries. The third edition, published since the death of the author, has been prepared and brought fully up to date by Mr. Godwin. The work is full of practical instructions for the guidance of the army surgeon in time of peace as well as of war, and contains also much that will be of great service to surgeons in civil life as well. It is issued in handy form, with a substantial cover, and is well adapted, as its name implies, for a handy reference-work to be carried in the pocket.

Diseases of the Joints. By Howard Marsh, F.R.C.S., Senior Assistant Surgeon to and Lecturer on Anatomy at St. Bartholomew's Hospital; Senior Surgeon to the Hospital for Sick Children and to the Alexandra Hospital for Hip Disease. With sixty-four illustrations and a colored plate. Philadelphia: Lea Brothers & Co. 1886.

This is one of the excellent "Clinical Manuals for Practitioners and Students of Medicine," several volumes of which we have already noticed in these columns. The book before us fully sustains the reputation of the series, if, indeed, it should not be regarded as one of the best that have thus far appeared. The little work is eminently practical, as such manuals should be, and, while the discussion of the pathological conditions found in the various joint-affections is carried to sufficient length, the greater part of the book is devoted to the subjects of diagnosis and treatment. The illustrations are good and the typographical execution is beyond criticism. The only fault we have to find with the book, and it is in our eyes a serious one, is that the author has little or nothing to say on the American method of treatment of chronic joint-diseases by means of traction, and what little he does say is in condemnation. Apart from this, Mr. Marsh's recommendations are sound, and his treatise deserves a place among the few standard works on diseases of the joints which are accessible to English readers.

Von Ziemssen's Handbook of General Therapeutics. Vol. V. New York: William Wood & Co. 1886.

The fifth volume of this important series is devoted to the consideration of orthopedics, including gymnastics and massage, and to hydrotherapeutics. The section on general orthopedics is from the pen of Professor Busch, of Berlin, and the translation has been prepared by Dr. Noble Smith. The latter, in a short preface, very aptly characterizes the work of Busch as "an elaborate essay rather than a systematic treatise upon orthopedics." It is none the less valuable, however, for this reason, and while the specialist may find it incomplete in some respects, the general reader will peruse its pages with profit, and cannot fail to find it a useful guide in the management of the various kinds of deformities likely to occur in his practice.

Massage as a Mode of Treatment. By William Murrell, M.D., F.R.C.P., Lecturer on Pharmacology and Therapeutics at the Westminster Hospital; Examiner in Materia Medica in the University of Edinburgh, and to the Royal College of Physicians of London. Second edition. Philadelphia: P. Blakiston, Son & Co. 1887.

This is the second edition of this instructive little brochure, which has been partly rewritten and enlarged, but is still of dimensions small enough to permit of its being read through in one evening. One can learn from it what massage is capable of accomplishing, although it goes but little into the details of the technique of this therapeutic measure.

The Medical Student's Essentials of Physics and Chemistry. By Condict W. Cutler, M.S., M.D., Physician to the New York Dispensary; Assistant Surgeon New York Hospital, Out-Door Department; late House-Physician Bellevue Hospital. New York: J. H. Vail & Co. 1887.

This is a very handy little work, which is well suited to the needs of the medical student, whose limited time will usually not allow him to study the more exhaustive treatises on these necessary, but too often neglected, subjects. The writer shows himself to be a master in the art of condensation, and the amount of useful knowledge stored up in these pages is more than is contained in many a more pretentious-looking volume.

Bau, Leben, und Pflege des Menschlichen Körpers. Für Schule und Haus. Von Dr. H. Dümling, Professor am Concordia-College zu Fort Wayne, Ind. St. Louis: Louis Lange Publishing Company. 1884.

This is a book treating in a popular way of the elements of physiology, anatomy, and the care of the body in health and disease. It contains much instruction suitable for the laity in matters of hygiene and the like, and also directions for their guidance in cases of emergency before the arrival of the doctor. It is a book that we would wish to see in the library of every German-American family, for were knowledge of the kind here given more wide-spread among the laity the labors of the physician would be immeasurably lightened.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, May 9, 1887.

ROBERT F. WEIR, M.D., CHAIRMAN.

DR. A. B. JUDSON presented a patient who was wearing

AN ISCHIATIC CRUTCH,

and gave a description of the instrument. (*Vide* THE MEDICAL RECORD, vol. xxxi., p. 721.)

DR. L. H. SAYRE exhibited an instrument made twenty years ago, on the same principle, for a case of luxation of the head of the femur into the thyroid foramen, of nine months' standing. After reduction was effected, a mechanical appliance was required to retain the head of the bone in its proper position; so an ischiatic crutch was made, and a ball-and-socket joint, etc., which answered very well while the patient was walking or standing, but which gave great trouble when sitting. He was therefore interested to know how Dr. Judson surmounted that difficulty, and it seemed evident that it had been accomplished.

DR. JUDSON said that the idea of an ischiatic crutch, of course, was not new, and it was only the special form of the instrument to which he wished to direct attention.

DR. HENRY GRISWOLD presented a specimen of

CYSTIC SARCOMA OF THE BREAST,

with the following history: The patient was thirty-eight years of age, who fifteen years ago had an abortion, which was followed by fever and a milk leg. At that time a small swelling was noticed near the nipple of the right breast, but it was not painful, nor did it increase in size very fast. But it remained, and seven years later, when she went to housekeeping, the nodule became painful and was constantly sore, due, as she thought, to working the elevator. About this time a second swelling appeared near the first. The breast then began to increase in size, and two years later—five years ago—she consulted Dr. Griswold, who found that the whole gland, apparently, was enlarged, with nipple uninvolved, freely movable, and not painful, and he suggested excision. Dr. Little was seen in consultation, who regarded it as chronic hypertrophy of the gland, and advised the local use of iodine ointment and the use of full doses of iodide of potassium.

Dr. Griswold saw the patient again in January last, when the breast was so much enlarged that it showed plainly through the clothing, in spite of her efforts to conceal it by dressing. He advised an early consultation with Dr. Weir, who recommended that it be removed, and the operation was performed on March 29th. The hemorrhage was slight and easily controlled.

THE AXILLA WAS OPENED AND EXPLORED,

but no enlarged glands were found. A drainage-tube was inserted, and the wound was united with catgut sutures. The patient was able to go to her meals on the eleventh day. Microscopic examination showed the tumor to be a cystic sarcoma.

DR. C. A. POWERS presented two patients illustrating the results of *conservative surgery* in severe injuries to large joints. The first, a man fifty years of age, was admitted to the Chambers Street Hospital in June, 1884, suffering from a

COMPOUND DISLOCATION OF THE RADIUS AND ULNA, COMPLICATED BY RUPTURE OF THE BRACHIAL ARTERY.

About half an hour before admission he had fallen fifteen feet into the hold of a canal-boat, the whole weight of the body being received upon the extended left palm.

The bones of the forearm were thrown backward, and the lower end of the humerus came through everything in front of it except the tendon of the biceps and the median nerve, which were pushed to the outer side. The bone protruded three inches through a large transverse wound at the front of the elbow, all its ligaments being ruptured except the posterior. Upon receipt of the injury there had been profuse arterial hemorrhage, which the patient himself checked by tying a handkerchief about the arm. Pulsation was lost in the radial and ulnar arteries, yet the hand remained fairly warm. Sensation was perfect at all points.

The most thorough antiseptic details were carried out, the ends of the brachial artery, as well as all other bleeding points, ligated, the dislocation reduced, forearm placed at a right angle, wound thoroughly drained, and a large antiseptic dressing of iodoformized gauze, peat, and borated cotton applied.

The hand remained warm, sensation good, and the dressing was not removed till the seventh day, when the wound was found to be aseptic and the condition of all the parts perfect.

The elbow was re-dressed at intervals of about a week, at each time being placed at an angle differing by about fifteen degrees from the preceding position. The wound slowly closed by granulation.

Moderate passive motion was begun on the twenty-ninth day, and on the fiftieth flexion and extension were all but perfect, pronation and supination being normal.

The patient now has a fair radial pulse, and

ALL MOVEMENTS ARE ABSOLUTELY NORMAL.

He uses the arm in his daily work, and knows no difference between it and its fellow.

Dr. Powers thought the following features made the case remarkable: First, the complete recovery of all joint-functions after such severe exposure of the joint-surfaces; second, the fact that the brachial was torn completely across, while the structures on either side of it—the bicipital tendon and the median nerve—escaped injury; and third, that the anastomotic circulation behind the condyles sufficed to supply the forearm and hand, the anastomoses in front of both the outer and inner condyles having been broken.

Dr. Powers' second case was one of

COMPOUND COMMINUTED FRACTURE OF THE TIBIA AND FIBULA, INVOLVING THE KNEE-JOINT.

The patient, a man forty-eight years of age, and of temperate habits, was admitted to the Chambers Street Hospital on November 20, 1886. A barrel of flour had fallen on his leg just previous to his admission. His knee-joint was greatly distended and markedly emphysematous; there was a wound of the soft parts, over the insertion of the sartorius, which would only admit the end of the finger, but through this the bone was felt to be badly comminuted.

The patient was etherized, a longitudinal incision some four inches in length was made at the site of the wound, and loose bone removed from the inner surface of the tibia over an area two by three inches, exposing the medullary canal to that extent. A longitudinal fracture through the head of the tibia entered the knee-joint. After the removal of bone so deep a cavity was left that it was found necessary to work back through the soft parts and make a posterior counter-opening for drainage. A large hæmatoma on the outer aspect of the leg was freely incised, the clot removed, and the cavity well drained.

Incisions were made into the knee-joint within, without, and above, the joint thoroughly irrigated with the bichloride solution (1 to 6,000), and rubber drainage-tubes inserted after Heuter's method.

The strictest antiseptic precautions were observed at all times, and a large dressing of iodoformized gauze, bichloride gauze, and borated cotton applied from the ankle

to the upper third of the thigh, with a plaster-of-Paris bandage over all.

NO ELEVATION OF TEMPERATURE OR OTHER UNTOWARD SYMPTOMS FOLLOWED.

Even the dressing was not disturbed until the twelfth day, when it was removed, and all wounds found to be absolutely aseptic. Silk was substituted for the rubber tubes in the knee-joint, and a dressing applied similar to the first. The dressing was again changed on the twenty-first day, at which time the silk was removed, as well as the rubber tubes which had hitherto drained the leg. Up to this time not one drop of pus had been formed.

Fenestra were now cut in the plaster splint, and the wounds of the leg dressed openly; they were closed by the sixtieth day, but there was delayed union, and it was not till three and a half months after the accident that union was firm.

At present there is flexion from full extension to an angle of one hundred and fifty degrees, and it is almost certain that the patient will regain complete use of the joint. Attention was called to the fact that the absence of any suppuration in this extensive injury proved that the antisepsis had been absolute.

THE CHAIRMAN remarked that one of the advantages of antiseptic surgery was that it was within the reach of all, and should therefore be practised by all. It also enables the youngest surgeon to get as good results as the oldest, and to the thoroughness with which antiseptic drainage was applied, in such cases as that reported by Dr. Powers, could be ascribed the success obtained. The method pursued was the best that could be adopted; that is, by an opening upon each side of the joint, and a third opening at the apex of the synovial sac. The same method is applicable to cases of exsection, and also where suppuration has already been established.

DR. J. A. ANDREWS then read a paper on

EXOSTOSES OF THE ORBIT AND THE NEIGHBORING CAVITIES.

He gave the following conclusion: In the osteomata which intrude into the orbit from the neighboring cavities, especially those of the frontal and ethmoidal sinuses, we have to deal with a disease which offers the best chances for successful removal when the operation is undertaken at an early period of its existence, before a diseased condition of the tissues (especially *suppuration*) surrounding the growth has set in, which must always constitute an element of great danger in connection with the operation.

There is another reason for operating just as soon as a diagnosis can be made, especially in the case of osteoma of the frontal sinuses—viz., no matter how small the orbital portion of the growth may be, an operation should be advised, because it is impossible, by the orbital portion alone, to judge of the real size and extent of an osteoma springing from the frontal sinuses; the orbital portion of the tumor may be the size of a pea, and yet the entire sinus be filled with the body of the growth.

In removing an osteoma from the neighboring cavities of the orbit, it is always better to break down the walls of the cavity through which it has made its passage into the orbit than to attempt to remove the growth from the cavity by attacking the body of the growth itself, since the latter is so hard (when ivory) that a chisel can be forced into it only by employing an unnecessary and harmful amount of violence.

He believed that even those osteoma of large dimensions which invade the cranial cavity may be successfully removed if we disregard the cosmetic effect of an operation and make a liberal exposure of the growth and remove it entirely, and always avoid allowing, as has been done, a portion of the growth to remain, merely because it intruded into the cranial cavity.

Search should always be made for polypi in the cavity occupied by the osteoma, and they should be completely removed.

The operation should always be performed under *strict antiseptic precautions*.

While it is true that the atmosphere has, as a rule, after such operations, free access to the cavity whence the tumor has been removed, and the dangers from atmospheric infection are not the greatest to be dreaded, nevertheless even this source can be excluded by appropriate dressings, and should not be neglected.

THE CHAIRMAN said that his interest in the paper had been great, because he had seen *five* cases, two occurring within the last two weeks. He had seen two cases in which the growths were removed; and in one, after chiselling away for a while, the forceps were applied and the growth twisted from its bed. He felt at the time that the procedure was rather severe, for it would not have been difficult to have invaded the cranial cavity by fracture. As it was, the orbital plate was broken.

So far as his personal experience went, it had occurred to him that there were two important surgical points to be borne in mind in the removal of these growths.

First, a large exposure should be made; and second, there was often associated with these formations in the upper part of the nasal cavities and frontal sinuses a certain quantity of decomposing mucus and pus, and a large opening was necessary to remove this material thoroughly.

DR. FRANK ABBOTT then read a paper (see page 43) on

IMPLANTATION OF THE TEETH.

DR. R. T. MORRIS asked if any difficulty had been encountered in the way of granulations crowding the implanted teeth out. He also suggested that it would be better to allow the pulp of a freshly extracted tooth to remain, to aid in the repair incident to giving the implanted tooth a firm position.

DR. ABBOTT thought it hardly possible that granulations would throw out the teeth; at least, nothing of that kind had yet occurred, so far as he knew.

So far as removal of the pulp was concerned, it was supposed many years ago that when a tooth was extracted and at once placed into a socket in another mouth the nerve and blood-vessels would unite. But it was soon learned that union did not occur; so it had been decided to remove the pulp and seal the cavity with some cement substance before the tooth is inserted.

DR. KINGSLEY said that Dr. Tonner was present, into whose jaw he had inserted two teeth that were removed from the jaws of other persons *eight years* before. (Dr. Tonner exhibited the teeth, which were firmly set, and which had given him no inconvenience.)

Dr. Kingsley continued, and said that his first case was that of an old maid who wished to have her irregular teeth put into shape, and this he did by removing two and making new sockets for them. The operation was performed last November, and the patient had worn them with great satisfaction and comfort ever since. He operated on Dr. Tonner last January, and in another case in December last, and with a good result, as seen in Dr. Tonner's case.

He stated that six months ago he regarded the operation as

THE RASHEST OF EMPIRICISM,

but to-day he did not know whether it was or not.

THE CHAIRMAN asked if the presence of the periosteum was necessary to success.

DR. KINGSLEY said that upon Dr. Tonner's teeth there were apparently little patches of dried periosteum. In his first case there was periosteum upon one root, but the other was entirely bare.

DR. BOGUE remarked that the operation did not originate with Younger, but with an American, in Paris, who observed that the teeth at the end of about two years dissolved. He thought that the question now was whether or no the teeth would be permanent. As to whether or

no actual circulation was established between the teeth and the surrounding parts, it had been demonstrated by means of the electric light that it had occurred.

Dr. Kingsley remarked that, even if the teeth did dissolve within two years, there were many persons who would prefer to have new ones set in preference to wearing a plate.

Dr. Tonner said he would undergo the operation every two years rather than wear a plate.

Dr. Kingsley said it might not be out of place to state that the teeth which Dr. Tonner wore were from the mouths of a son and a daughter of a wealthy man, and a Republican in politics. Whether

THESE ROOTS,

thus transplanted, would bring forth good fruit was something that had not yet been decided.

The Section then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE RECENT APPOINTMENTS AT GUY'S HOSPITAL—CULTIVATION EXPERIMENTS WITH MALIGNANT GROWTHS—ABDOMINAL CYSTS—THE STUDY OF ALCOHOL—THE HOSPITAL SUNDAY FUND—THE PRINCE AND PRINCESS OF WALES AT THE LONDON HOSPITAL.

London, June 23, 1887.

Changes in the medical staff of Guy's Hospital have recently been very rapid. Four deaths in as many years have naturally caused great changes. Add to this that the staff has been enlarged, and it will be seen that promotion among the juniors has been correspondingly rapid. Three assistant physicians have just been elected at once. Two of these were to fill vacancies, and one to take the extra appointment recently created. Some dissatisfaction exists regarding the mode in which this last appointment has been filled. It was announced on this occasion that—contrary to precedent—candidates who were not Guy's men might apply. Several did so, and to their astonishment a gentleman was selected to fill the post who has only been qualified two years, and who has just emerged from the house-physiciancy at another hospital. It is true that he has claims to literary and social distinction, having been the captain of Eton School, and graduating at Cambridge, in 1880, as Senior Classic. But these are not medical distinctions, and several of those who have been passed over feel that, from a professional stand-point, their claims were greater and their experience certainly longer.

Messrs. Ballance & Shattock have been performing some cultivation experiments with new-growths. The results were exhibited at the last meeting of the Pathological Society. Pieces of carcinomata of the breast, removed by operation, had been transferred immediately to tubes of solidified serum, agar-agar, and Koch's beef peptone gelatine, and incubated at 100° F. for various periods—in one case for thirty-three days. In every instance the growths were sterile, and portions of testicle, submaxillary gland, kidney, and muscle remained equally so. Their results, therefore, corresponded with those of Mr. Watson Cheyne in 1879. Messrs. Ballance and Shattock concluded from their experiments that the parasite of cancer must differ in its life-history from those already known, in that it did not admit of cultivation in any of the ordinary media. They were led to these experiments with new-growths, as they were persuaded that their essential pathology must be similar to that of the specific diseases.

At the last meeting of the Clinical Society a paper of especial interest was one by Mr. Rickman Godlee, dealing with the history of three cases in which large abdominal cysts formed after injuries. One was a little girl of four, in whom the left ureter was ruptured. A large cystic tumor containing urine developed. The kidney was ultimately removed, and the child made a good recovery. The second case was that of a man of twenty-three, who was run over by a heavy wagon. The third was that of a boy, aged seven, who was knocked down by a van, but not run over. In each of the latter cases, on tapping, a turbid fluid containing urea was drawn off. Both cases recovered. Mr. Golding Bird remarked that urea was found in most of the tissues and fluids of the body, so its presence did not necessarily point to a renal origin of the cysts. Mr. Barker referred to two cases of his own in which urea was also found.

The study of the action of alcohol in health and disease is not one which is at all neglected by the present-day practitioner. Three years ago a society was formed having for its title "The Society for the Study and Cure of Inebriety." Membership is not restricted to total abstainers, as is the case with the older body known as "The British Medical Temperance Society." The latter has just completed its tenth year, though its members are not yet so numerous as to give one the idea that medical men are all hastening to become teetotallers. It is, nevertheless, a flourishing organization. The annual meeting took place last week. Among other papers was one by Dr. Walter Pearce, of St. Mary's Hospital, on a case of acute cardiac dilatation from alcoholism. At the last meeting of the Clinical Society, Dr. Robert Maguire brought forward several similar cases; while at the Medical and Chirurgical Society, Dr. David Finlay read a paper on three cases of multiple neuritis, due to alcohol and causing paralysis. Judging from recent work, alcohol does not seem destined to have its influence overlooked. In the discussion on Dr. Finlay's paper, Sir Dyce Duckworth remarked that it was not always easy to elicit a history of alcohol. Probably he does not go on the same tack as that adopted by a prominent member of the British Medical Temperance Association, who remarked to me, recently, "When a patient begins to tell me he doesn't drink, I always suspect him." There is no reason, though, why the proverb *Qui s'excuse s'accuse* should not be borne in mind in making a medical diagnosis, as in other matters.

Special efforts are to be made again this year on behalf of the Hospital Sunday Fund. Last year meetings were held in various parts of London, presided over by speakers of eminence, who undertook to plead the cause of the hospitals. The same course is to be adopted now. Among the speakers already announced are the Prime Minister, Lord Randolph Churchill, Cardinal Manning, Mr. Spurgeon, the Bishop of London, Sir Andrew Clark, Mr. Henry Irving, and the Lord Mayor.

On Saturday afternoon the Prince and Princess of Wales paid a visit to the London Hospital, for the purpose of opening the new buildings. These are of some extent and consequence, comprising a new nursing-home, a new library, and extensive additions to the college, including a residence for students. The college buildings were only erected in 1854, and the present is the third and most important enlargement which has taken place since that date. In their present form they are very extensive, and are admirably adapted for the purpose for which they are designed. A large audience was present, including most of the staff, and great enthusiasm was evoked in the neighborhood by the royal visit, most of the masts and banners which had been put up to welcome the Queen the week before being left standing for the occasion.

OUR VIENNA LETTER.

HEALTH OF BILLROTH—DITTEL'S TREATMENT OF STONE IN THE BLADDER—MULTIPLE VESICAL CALCULI.

Vienna, May 29, 1887.

Professor Billroth continues to improve in physical condition. During the past week he has been out of

bed each day, and is fast gaining strength. He will not, however, deliver any more lectures this semester.

In the treatment of vesical calculus Professor Dittel rather favors lithotripsy, when it is possible. In cases in which it is probable that a very hard stone, an encysted stone, a "pipe" stone, *i.e.*, one that sends prolongations from the bladder into the urethra or ureters, or a stone with a foreign body as a nucleus, is present, or a urethral stricture exists, he performs the operation of incision. In this particular he has shown a decided preference for the high, or suprapubic, operation. In any case where the patient is very old, or the stone is small, he invariably crushes.

In the high operations he incises in the linea alba just above the pubes. The bladder is distended with carbolized water, and a colpeurynter is introduced into the rectum and distended with water. This procedure throws the bladder up against the abdominal wall in front.

When the peritoneum is reached it is pushed upward without injury, and the bladder exposed and opened. He uses no sutures, but, introducing a drainage-tube, packs the wound with iodoform gauze and covers with the ordinary dressing. A catheter is also introduced through the urethra and allowed to remain there for the first day. In several cases which he has had of this kind very excellent progress is being made. No fever has arisen, and the drainage of the bladder is complete.

In a few cases, where neoplasm has been a complication, this incision has made the removal of these growths a very easy matter. In none of the operations was hemorrhage a consequence.

To-day an interesting case was met with in Dittel's clinic, in that twenty-four calculi were removed from one bladder. The smallest was the size of a hazel-nut, and the largest that of a horse-chestnut. The calculi were rather flattened, and of both phosphatic and uric acid composition. In this case the median incision was made.

INDISCRIMINATE URETHRA-CUTTING.

To the Editor of The Medical Record.

Sir: I wish to protest against the indiscriminate urethra-cutting so much now in vogue, especially by the younger men. A man has a stricture, no matter where its location or its character, and urethrotomy is suggested, not the last, but the first thing. They tell us a fatal termination is the exception, and it may happen from simple catheterization. True, but who will say that there is no additional danger from a urethrotomy or a divulsion. We have no right to assume any risks for our patient, not so much as we would be willing to take ourselves. The golden rule, "Do unto others," etc., should be heeded in this as in every relationship of life. I would lay it down as an axiom that a stricture should not be cut that is amenable to dilatation. In the enthusiasm of youth there is a fascination in the brilliant results often obtained from urethral surgery. To relieve a man, as if by magic, who has been a patient sufferer for years, is a "consummation devoutly to be wished," but not generally at risks about which he knows nothing. I have not taken the trouble to obtain the results of internal urethrotomy as furnished by our hospitals in this city. I hope some one will do so, and then, when all the facts are known, I think you will agree with me that most men would "rather suffer the ills they have than fly to others they wot not of." I am conscious of being wofully out of fashion in speaking thus, but I do so from a strict sense of duty. No one knows better than I that some strictures will not yield to dilatation, but I am speaking against the growing tendency to cut all strictures. As for divulsion, I will only say that, as performed with the typical instruments, it is an unprecise, unsurgical procedure. I have offered to sell my divulsors for old iron, but which I will rather keep as a memento of the times; but I have not used them for years, and do not expect to again.

Of the various forms of non-inflammatory and inflammatory thickening of the coats of the bladder from obstructed micturition, the capacity of the viscus is, as a rule, diminished in urethral obstruction, while generally the reverse obtains in prostatic obstruction. In a specimen I have before me of concentric hypertrophy of the prostate, there are the usual manifestations of hypertrophy and thickening of the coat of the bladder, and yet the capacity of the organ is materially increased. The history of the difficulty, as obtained from a study of the bladder, I take to be briefly as follows: A disease of advanced life, insidious in its progress and in natural sequence of events; hypertrophy of prostate; obstruction to urination; hypertrophy of muscular coat; high tension at some time of the vesical walls, accounting for the dilatation; bladder could not empty itself; residual urine; chronic inflammation, known as vesical catarrh; and, lastly, extension of that inflammation to the connective-tissue coat, in which *infiltration and organization* have taken place. The bladder is rendered inflexible and indurated, and the hypertrophied muscular coat unable to obliterate its cavity. One other point, and I have done. In speaking of hypertrophy of the muscular coat and sacculation of the bladder, Mr. Guthrie called attention to a peculiar sensation communicated to the hand by the catheter, as if a series of blows had been given the instrument with the expulsion of the last few drops of urine, which he called the "fluttering blows of the bladder." Mr. Guthrie thought that these were caused "by the descent of the pouches containing the urine, and by their being more or less solid substance, they fell against the instrument or were brought forcibly against it by the muscular efforts of the bladder in contracting on the evacuation of the last drops of urine from its cavity." But therein, I am sure, Mr. Guthrie was mistaken, for I have repeatedly called the attention of my internes to these "blows" in subjects in whom we had no reason to suspect anything like sacculation of the bladder. But I do not remember ever to have gotten them except catheterization was done when the patient was standing, never in the recumbent posture.

Alexander W. Stein, M.D.

New York.

SOLID TUMORS OF THE OVARY.

To the Editor of The Medical Record.

Sir: I find that in The Medical Record of April 9th Dr. Matthew Mann, of Buffalo, is reported as follows: "Mr. Tait had said that solid tumors of the ovaries did not occur at all, but that he was wrong, as a study of the literature of the subject would show." If Dr. Mann will turn to page 158 of my book on "Diseases of the Ovaries," published in 1883 by William Wood & Company, New York, he will find there a description of fibromatous tumors of the ovary, and a detailed account is given of the first case in which I operated, so far back as 1873; also of the post-mortem of a case which I made in 1869; and, altogether, the description of such cases occupies no less than eight pages of my book. It is, therefore, difficult to understand how Dr. Mann, supposing he has been correctly reported, has arrived at his conclusion.

I am, sir, yours, etc.,

Lawson Tait.

7. The Crescent, Birmingham, June 8, 1887.

TEST-TYPES FOR SCHOOLS.

To the Editor of The Medical Record.

Sir: Will you allow me, through your journal, to call attention to a card of test-type, recently published for, the use of schools and other educational institutions. Oculists and others interested in sanitary and prophylactic reform have long recognized the value, and, indeed, the necessity, of some measure by which the invasion

and increase of myopia and other diseases to which the student is liable may meet with early recognition and prompt treatment.

Periodical examinations of all the scholars in attendance on such institutions would, no doubt, more than repay the expense, the trouble, and the inconvenience of such examinations. But propositions to introduce such into the regular routine of school-life have been universally neglected by those who have authority in such matters. This is probably on account of the temporary inconvenience and disturbance of school-work which would attend such a useful innovation.

DR. DENNETT'S TEST TYPE
FOR THE USE OF SCHOOLS AND COLLEGES
DISTANCE 5 METRES OR 16 FT.
2 4 1 6 5 8 9 0 7 3
B S Q O Z P N H R K F C G
M W Y V T A I U E D J X L
E M Ǝ M E M Ǝ
MEYROWITZ BROS. OPTICIANS NEW YORK

It has been more than once proposed to have these examinations made by the teachers themselves; but the test-cards in general use among oculists are confusing to anyone not accustomed to them, and would not ordinarily be brought into requisition often enough to familiarize the mind of the occasional examiner with the significance of the results obtained. On the card referred to there is only one set of characters (letters and figures), each one of which can be distinguished by the normal eye at the distance of five metres or sixteen feet. Beneath is a statement of the distance at which they ought to be seen.

A card like this fastened to the wall of every class-room would prove of inestimable value to some, and of use to all. No one in every-day life has even an approximate idea of what the healthy eye ought to see, and the mere fact that a child grows up with such a standard as a familiar object before his mind is unquestionably a great advantage. But more than this is the advantage which each scholar will possess of being able at any time to examine his own eyes, and know surely whether they are as good as they ought to be or not. Of course a rough estimate of the amount and importance of any visual impairment can be made by noting the actual distance at which the letters can be clearly distinguished. But it was not thought best to designate any particular grade of deterioration that should excite alarm and induce the child to seek professional advice, but merely to place before the scholar the means of noting such failure. So many things would have to be considered in each individual case that no general rule could be made. But the fact that any well-marked impairment of sight has taken place should lead each particular scholar or his parents to consider the advisability of having the matter more thoroughly investigated.

Every physician who is in any way connected with the public schools, or interested in the management or patronage of other educational institutions, will see the advantage of placing such a card in every class-room, and of recommending it to the attention of every new scholar.

Hoping that your valuable journal will be glad to give publicity to this matter, I need only add that the cards are comparatively inexpensive and may be obtained at any time from the publishers, Messrs. Meyrowitz Brothers,

I remain, yours very respectfully,

WM. S. DENNETT, M.D.

31 WEST FORTY-SECOND STREET, April 15, 1887.

THE ALLEGED CASES OF BERIBERI IN NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE MEDICAL RECORD of February 19th I find an article entitled, "A Short Study of Beriberi," etc., by Dr. I. West Roosevelt.

Having been asked, on the eve of leaving for Japan, to assist in a discussion of the disease beriberi at a meeting of the Academy of Medicine, I was much interested in the reported appearance of this strange disease in the manner described in Dr. Roosevelt's paper, and in brief medical notes at the time in the various New York journals. The author's question at the close of his summary of the cases forming the basis of his paper, "Are they beriberi?" is not altogether a surprise to me. As the frankness with which he asks this question seems to invite an equally frank reply, I shall venture to answer it, in all due respect to the author, in the negative.

At least I would say that the cases embodied in the report did not appear to me to have been the beriberi which I had had the opportunity of observing and studying for eight years in a large hospital of which I had charge, in one of the centres of severe prevalance of the disease in the country.[1] The time being very considerable since Dr. Roosevelt's paper appeared, I fear interest in the subject has died out. I shall therefore but briefly give the reasons why I am disposed to think the cases reported as having occurred on the ship Henry S. Sanford were, as I have intimated, not beriberi.

1. Hong Kong, as far as I am aware, is *not* an infected port,[2] or a port where beriberi prevails, as stated by Dr. Roosevelt. Aside from the fact that I never heard that the disease prevailed in Hong Kong, is the one that, of the thousands of Chinese who yearly go from that place (Hong Kong) to San Francisco, few, if any, suffer from beriberi, either on the voyage or after their arrival in California.

2. I do not know of a single well-authenticated case of beriberi occurring in a European in this country, showing a peculiar want of susceptibility in them to the disease.

3. The disease is almost unknown except where the chief article of diet is rice, which does not seem to have been the case on the ship Sanford.

4. Bad or poor food and bad water are not, according to my observation, a predisposing cause to the disease, much less an exciting one, as it is the well-fed and well-to-do who, as a whole, are the greatest sufferers from beriberi in this country.

5. The symptoms of the cases and the post-mortem appearances were not, according to my mind, sufficiently well defined to justify a diagnosis of beriberi.

I have very often been greatly puzzled to make a diagnosis of the disease presenting similar histories and symptoms to the cases which occurred on the Sanford, even in a locality of known prevalence of the affection.

I am well aware, in view of the amount of expert evidence which was brought to bear on the cases under consideration in favor of a diagnosis of beriberi, that my reasons for an adverse opinion are wanting in that definiteness which will be likely to carry conviction to those who have committed themselves on the subject.

It is but a fair question for these persons to ask, If the cases were not beriberi, what were they? This I will not pretend to say. It is much easier to say, especially in medicine, as we all know, what a disease is not than what it is.

Still, in view of the comparatively large experience which I have had with beriberi, I do not feel that it is altogether presumption on my part to have given a frank

[1] See my paper (forty-eight pages), Beri-beri or Kakke in Japan, Chinese Customs Medical Report, 1879–80. Also a brief and, for want of space, a very unsatisfactory, article in Pepper's Practice of Medicine by American Authors.

[2] The term "infected port," as applied to Hong Kong in this connection, is not warranted, as it is by no means proven that beri-beri is an infectious disease.

expression of my opinion, whatever may be its value, in reply to the author's question, "Are they (the cases) beriberi?" D. B. SIMMONS.

TOKIO, JAPAN, April 24, 1887.

New Instruments.

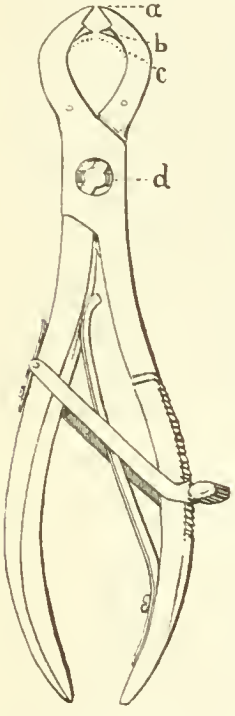
A NEW FORM OF BONE-HOLDING FORCEPS.

BY GEORGE ARTHUR, M.D.,

PASSED ASSISTANT SURGEON, U.S.N.

THE holding forceps at present in use are either so heavy and unwieldy as to seriously inconvenience the operator, particularly in exsections in which small bones are to be removed, *e.g.*, those of the carpus or tarsus, or are insecure and apt to slip from the bone.

The modified forceps (see figure, which represents half the actual size) are designed to obviate both these disadvantages.



The teeth at *a* are fixed as in the ordinary forms, and do not at any time change their position relatively to the rest of the instrument. Those at *b*, however, when the bone is grasped and strong pressure made, are forced away from the stationary teeth, *pari passu* with their entrance into the bone, by the included portion (of bone) acting as a wedge, into the position indicated by the dotted lines and lettered *c* in the cut.

The effect of this movement of the inner teeth, which is very slight, is to make both sets, which are sharp and serrated, push their way *under* the cortex of the bone, and, being held in that position by the catch on the handle, are locked into it, so that it is impossible for them to slip or loosen their hold, without breaking through the overlying bony substance.

When it is desired to release the instrument, the catch on the handle is pushed up, and pressure being thus removed, the movable teeth are restored to their original positions by strong pistol-springs, and the jaws can be separated.

The instrument, including the inner teeth and the springs that operate them, can be readily separated and taken apart for cleansing. It can be made, if desired, with a double pivot-hole in the female blade, so as to adapt it to larger bones, without increasing its size or weight; it was designed, however, particularly for wrist and ankle-joint exsections, for which purposes the grasp is sufficiently broad. F. Arnold & Son, of Baltimore, are the makers of the instrument.

A NEW NEEDLE-HOLDER.

BY G. W. SQUIRES, M.D.,

EAST AVON, N. Y.

THE following is a description of a needle-holder which will be found to be an excellent instrument for sewing up almost all kinds of wounds which can be united by sutures. I call it Squires' counter-pressure needle-holder. It is made on the principle of a pair of shears. It is six inches long from the end of the handle to the needle. The parts are fastened together near the handle by a screw. There is a spring-catch in the handle to hold the edges of the wound in place while the suture is being tied. A short needle is used, which is held in place by a cup-shaped socket, constricted in the middle by a spring, which admits the needle and thread. The opposite shaft has an oval disk with a hole in the centre for the needle to pass through. There is a slot in the side of the disk leading to the needle hole. The needle is threaded, placed in the receiving cup, the edges of the wound are approximated, and the handles are then closed, thrusting the needle through the edges of the wound, and protruding through the hole in the disk. It is then drawn through and the sutures are tied. The instrument is displaced by the thread slipping through the slot in the disk. By this instrument nice, neat sutures may be made, and the edges of the wound may be easily and closely approximated.

A GUARDED TENACULUM FOR FACILITATING THE REMOVAL OF POSTERIOR TURBINATED HYPERTROPHIES.

BY E. P. SWASEY, M.D.,

NEW BRITAIN, CONN.

THE difficulty of wiring posterior turbinated hypertrophies, and especially of retaining these growths within the wire-loop, has probably been experienced by others besides the writer. In the hands of those who are not experts in this department of surgery, the little instrument here illustrated, one-half its real dimensions, and

which is a modification of the "fixation needle" devised by Dr. William C. Jarvis, of New York, will be found to facilitate the removal of these growths. When employed the instrument is first closed and then introduced along the floor of the nares, with the convexity of the hook upward, until it has reached its destination. The needle is now withdrawn until its point is within the tube, the instrument turned flatwise, then pulled toward the operator, when the beats will be felt to engage the hypertrophied tissue. If necessary, the needle may be pushed forward in order to retain the instrument in position while an inspection is being made. If a sufficient amount of the growth is found to be engaged, the needle is pushed home and secured by the set-screw. The "Jarvis snare" can be now introduced, the wire-loop being passed around the handle of the tenaculum. In order to facilitate this procedure, the instruments should be held parallel to each other, the loop being in this manner urged beneath the tenaculum, until it reaches the hook, when it will be felt to spring over the end of the director. The practice of a posterior rhinoscopic examination will demonstrate the accuracy of the wire's adjustment. A slight motion in different directions may be required to urge the wire still farther toward the base of the growth. The hypertrophied turbinated tissue can be now slowly severed from its attachment.

THE MIXTURE OF CHLOROFORM AND ETHER AS AN ANÆSTHETIC.—Dr. Rose, of this city, criticizes the recommendation of Dr. Nilson to use a mixture of chloroform and ether in certain cases for the production of anæsthesia. He writes: "It is always a delight if we can prescribe a pure and simple article instead of a compound. But, as Nussbaum says, there are many who are not contented with a pure and simple prescription, they do not feel quite well in such case, they commence at once to mix, and finally they do not know themselves what they are dealing with. A mixture of ether and chloroform, according to Nussbaum, acts as ether if this drug, and as chloroform, if the latter is even in predominating quantity."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 26 to July 2, 1887.

McKEE, J. C., Major and Surgeon. Granted three days' leave. S. O. 149, A. G. O., June 29, 1887.

BEALL, GEORGE T., Captain and Medical Storekeeper. Granted four months' leave of absence. S. O. 150, A. G. O., June 30, 1887.

CHERBONNIER, A. V., Captain and Medical Storekeeper. Directed to take charge of office, and perform duties of acting assistant medical purveyor in St. Louis, Mo., during absence on leave, of Captain George T. Beall, medical storekeeper, now performing those duties. S. O. 150, A. G. O., June 30, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 2, 1887.

DEANE, C. W., Passed Assistant Surgeon. Ordered to the Naval Rendezvous, San Francisco, Cal.

HARRIS, H. N. T., Assistant Surgeon. Ordered to the Naval Hospital, Mare Island, Cal.

GORGAS, A. C., Medical Director. Remain on present duty until December 31, 1887.

CLEBORNE, C. J., Medical Inspector. Remain on present duty until December 31, 1887.

MACKEY, BENJAMIN F., Surgeon. Remain on present duty until December 31, 1887.

BROWNE, J. MILLS, Medical Director. Will remain on present duty as member of Retiring Board until June 30, 1888.

DEAN, RICHARD C., Medical Director. Will remain on present duty as member of Retiring Board until June 30, 1888.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 2, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	3
Scarlet fever	37	11
Cerebro-spinal meningitis	2	1
Measles	20	5
Diphtheria	132	58
Small-pox	3	0
Yellow fever	0	0

HOW CAN THE ACCOUCHEUR BEST GUARD THE PERINEUM WHILE THE FŒTAL HEAD IS PASSING?—Dr. Berry Hart considers this often-discussed question under three headings (*Edinburgh Medical Journal*, April, 1887). 1. *The relations of the uterus and its contents when the normally rotated fœtal head is beginning to distend the perineum.* At this period of the labor the lower uterine segment, cervical canal, and pelvic floor have been canalized by the retracting uterus elongating and pushing the fœtal contents downward. The whole fœtus is compressed and packed together, with the chin flexed on the sternum, and the occiput leading. The perineum or sacral segment is being driven back, its lower end elongated and thinned, and the vulvar cleft, chiefly in its lower part, *i.e.*, below the level of the vestibule, greatly distended. Uterine retraction sets up in the fœtus and retained liquor amnii a general-contents-pressure, which is distributed over that part of the skull periphery lying below the girdle of resistance. The diameters of the girdle of resistance will vary greatly, according to whether the occiput or sinciput dips. In the latter case the antero-posterior diameters will be increased, and the risk of tear augmented in like proportion. The demonstration of this belongs to elementary obstetrics. In taking (2) *the consideration of how the fœtal head should pass the perineum so as to have a minimum of tear*, I have first to point out that the term extension of the head, as the fourth consecutive movement of the labor mechanism, is a most misleading one. It implies what I have already denied—that the chin leaves the sternum while passing the perineum; and that during the anterior fixation of the occiput under the pubic arch, antero-posterior and increasing diameters of the fœtal head form the antero-posterior diameters of the girdle of resistance. I deny *in toto* that the chin leaves the sternum, and I hold that this fixation of the occiput and descent of the sinciput is not the best or normal mechanism. The best mechanism to avoid tear is for the occiput to lead, for the head to be driven on by a steady movement of translation, any rotation on a bi-parietal axis so taking place as to favor occipital dipping and never dipping of the sinciput. It is easy to see how the erroneous idea of extension arose. The attendant, while the patient lay on her left side, watched the passage of the fœtal head from behind, saw more of the anterior portions of the head appear, and accounted for it by extension. We now pass on to (3) *a description of how the medical attendant can best guard the perineum, so as to avoid undue tear.* All the attendant can do, apart from the familiar means of relaxing perineal spasm by chloroform and hot applications, is to prevent the sinciput being forced down in advance of, or faster than the occiput. He restrains the fœtal head from passing too rapidly. He thus has always to get the occiput to lead, and to get it fully born first if possible. So far as I can judge, the best way of doing this is as follows: With the patient lying, of course, on her left side, the attendant places the thumb of his right hand, guarded by a napkin soaked in hot sublimate, in front of the anus and presses it gently there. The pressure is not in the direction of a line joining his thumb and the pubic arch, but nearly in that of the axis of the pelvic outlet. By this, descent of the sinciput is hindered, and that of the occiput favored. When the latter is beginning to pass under the pubic arch, the fingers of the same hand are placed between it and the apex of the arch, so that when the occiput has cleared the arch the fingers are passed toward the nape of the neck, and the head thus grasped in the hand, the thumb lying over the sagittal suture. This gives one complete command over the head, which is now engaging in the diameters between the nape of the neck and forehead and face, and allows the whole passage with as little tear as possible.

THE PRACTICE OF MEDICINE IN FRANCE.—The following are the principal features of the new bill about to be presented to the Chamber of Deputies relative to the practice of medicine in France. Medical practice in France is forbidden to all persons excepting those who hold the diploma of doctor or of officier de santé, which is granted by the French Government after examination by a medical faculty, preparatory school of medicine, or school of pharmacy, recognized by the State. Foreign physicians, of whatever nationality, are only allowed to practise their profession in France on passing the examinations required by the French medical faculties. A dispensation, however, may be granted in such cases, in accordance with a decree of the Council of Public Instruction; but in no case shall this dispensation extend to the whole examination. Officiers de santé must be assisted by a medical man, except in urgent cases, in all important surgical and obstetrical operations. They are forbidden to practise in the chief towns of departments and arrondissements, and in cities

of over ten thousand inhabitants. Experts, whether physicians or surgeons, can only be replaced in law courts, hospitals, and asylums, by doctors. The practice of dentistry is forbidden to all persons not provided with the diploma of doctor or officier de santé. Nevertheless, any dentist over thirty years of age, who can show by his license that he has practised his profession for two years before the promulgation of the present act, is allowed to continue to do so. This permission, however, does not include the right of administering anæsthetics. Midwives are permitted to practise only when provided with a diploma of the first or second class, delivered by the French Government; they are forbidden to use instruments or to prescribe medicines, except in extreme cases, but they may vaccinate. Doctors, officiers de santé, and midwives are required to have their diplomas registered within one month after taking up their abode in the place where they intend to practise. Medical students who are hospital assistants, and those who have finished their studies, are authorized to practise without a diploma in the case of an epidemic, or as substitutes for a doctor of medicine. The simultaneous practice of medicine and pharmacy is forbidden, even to persons holding both diplomas, except in cases where the nearest drug-shop is over four kilomètres from the medical man's residence; in that case he is authorized to dispense medicines for the exclusive use of his own patients. Whoever illegally practises as a medical man is punished with a fine of 100 to 500 francs; and in the case of a second offence the fine may be doubled and accompanied by imprisonment (fifteen days to one year). The wrongful assumption of a title is punishable by a fine of 1,000 to 2,000 francs; for a second offence this may be doubled and accompanied by imprisonment (six months to one year). The use of a foreign medical title without previous receipt of a diploma from the French Government comes under this category. Doctors, officiers de santé, and midwives practising pharmacy are fined 100 to 500 francs, which is doubled in the case of a second offence, with the addition of imprisonment (fifteen days to one year). Whoever practises as a doctor of medicine without having first registered his diploma is fined 100 to 500 francs. In the case of legal proceedings against persons guilty of the illegal practice of medicine, doctors or associations of doctors regularly authorized, and interested in the proceedings, may claim damages.—*The British Medical Journal.*

"Massage" for the Treatment of Corneal Opacities.—There are, perhaps, no affections of the eye which cause more disappointment to both surgeon and patient than the opacities of the cornea which are left by keratitis and ulceration. After prolonged and varied treatment the inflammation, which has perhaps undergone many remissions and relapses, finally subsides, only to leave an eye which is practically useless, owing to the loss of transparency of a great part of the cornea. So many different modes of treatment have been suggested for this condition, and, after trial, have been abandoned as useless, that there is much natural scepticism as to the efficacy of any new proceeding, and most surgeons trust to the effect of time and Pagenstecher's ointment. In a paper, read before the British Medical Association at Brighton, Mr. Snell redirected attention to friction or "massage," as a mode of hastening the disappearance of corneal opacities. Although not capable of effecting all that was at one time claimed for it, it has now stood the test of time, and may fairly be said to have met with more success than any other single mode of treatment. First proposed by Pagenstecher, in 1872, as a means of hastening the absorption of corneal opacities, it has since been advocated by many writers. But Dantziger (*Archiv für Ophthal.*, xxxi., 3, 187) has shown that its sphere of usefulness can be considerably enlarged, if it be preceded by the mechanical removal of the opaque corneal tissue by scraping. The employment of "massage" during cicatrization then prevents the newly deposited tissue becoming opaque. Although there is some difference of opinion on points of detail, the following is probably the best mode of employing the "massage." The inner surface of the eyelid should be lubricated, preferably with Pagenstecher's ointment; the pulp of the finger is then laid on the lid, and the latter moved to and fro over the cornea with great rapidity, in a direction radiating from the centre of the cornea. The operation is continued for about a minute, and repeated daily, as long as improvement continues to take place. The results of Dantziger's cases would encourage us to persevere for a considerable time.

Stunning and Burning from Electric-Wires.—As an incident in the development of the use of electricity for mechanical purposes, a class of injuries has arisen which present certain peculiarities. "Linemen" and "electric-light trimmers" are the ones most frequently injured; and in the pursuit of their vocations, as in every other dangerous occupation, there develops a certain carelessness which, at times, proves fatal. As the extensive use of electricity is of comparatively recent date, only a few fatal injuries of this description have been published. The remarkable instantaneous death of a workman at the Health-Exhibit in London, and a similar death of a sailor on the Russian Imperial yacht Livadia, led Sheild and Delépine to carefully note the post-mortem appearances in a case that came under their observation, which they have recorded in the *British Medical Journal*, March 14, 1885. They found that the blood remained fluid, and the heart was empty. They believe that it is quite possible to recognize an electric burn, not alone from its gross appearance, but also from certain peculiar microscopical appearances that exist in the blistered integument. The human body is, fortunately, a poor conductor of electricity; and it has been said by certain electricians that a wire (in circuit) transmitting enough electricity to light fifteen lamps may be handled with impunity, if the circuit is not broken. Occasionally, however, a "lamp-trimmer" brushes against the wire with a wet rubber coat, or touches it with damp hands, thus breaking the circuit, and receiving a severe shock and burn. Three cases of this character occurred in Boston last autumn, where men received an electric shock in the above manner. They were rendered unconscious, fell to the ground, and sustained, in addition to the bruising from the fall, a severe shock and local burns. The burns were peculiar in that the tissues were completely destroyed, the surrounding parts anæsthetized, and that, at first, there was no local congestion of the surrounding skin; the reparative process was very slow and tedious. The period of unconsciousness varied with the severity of the shock, which, in two of the cases, was recovered from in a few days. Professor George Buchanan reports the case of a laborer who was stunned and burned while working in the vicinity of a Brush light. The victim was engaged in handling a crane. By the wire of the light coming in contact with a chain attached to the crane, he was brought into the circuit. He was instantly "doubled up," his hands spasmodically grasped the chain, and in this position he was held for four minutes, until the lamp and chain were disconnected. The amount of shock was slight, but a full hour elapsed before consciousness returned; he then complained of a sensation of heat in the abdomen, and slight dimness of vision. There was a slight vesication on the hands, and at the point on the sole of the foot from which the current passed into the ground a charred surface, two inches square, remained. It is certainly remarkable that so powerful a current could pass through the foot without causing more injury in its passage. The treatment of these cases is essentially that adopted for severe nervous shocks, the burns being treated as their intensity may demand.—*The Boston Medical and Surgical Journal.*

FUNDAMENTAL IDEAS REGARDING THE SUPPORT OF THE BODY PROPER FOR THE CURE OF DISEASE, THE RELIEF OF SUFFERING, OR THE ARREST OF DEFORMITY.

BY MILTON JOSIAH ROBERTS, M.D.,

PROFESSOR OF ORTHOPEDIC SURGERY AND MECHANICAL THERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING ORTHOPEDIC SURGEON TO THE CITY HOSPITALS ON RANDALL'S ISLAND; CONSULTING ORTHOPEDIC SURGEON TO THE WOMAN'S HOSPITAL, BROOKLYN, ETC.

IF mechanical support is to be utilized as a therapeutic agent in the cure of disease, the relief of suffering, or the arrest of deformity, a definite idea should be entertained by the physician as to the *modus operandi* of the production of its beneficial effects. Otherwise, he who uses such means may some day wake up to find that he has been the credulous supporter of the unsubstantiated assertions of authority, or the blind follower of the teachings of tradition, rather than an intelligent institutor of remedial measures the *rationale* of which he thoroughly comprehends.

Spinal caries.—First, let us see what changes take place as the result of spinal caries, or Pott's disease. Viewing the normal spinal column laterally, stripped of its appendages, we see it presents a curvilinear outline; that the vertebral bodies, with their respective processes and articular facets, alternately rest upon and are supported by intervertebral substances. When caries of the spine has progressed to the stage of deformity, the anatomical relationships of the different parts of the vertebral column to each other become changed.

A good idea of the disastrous nature and extent of the changes which take place when the disease is not properly treated from the first, can be gained by an inspection of Fig. 1. This figure represents a longitudinal sectional view of the vertebral column of an adult, aged thirty-five years, who had caries of the eighth, ninth, tenth, eleventh, and twelfth dorsal, and first lumbar vertebræ. It was drawn, from an actual specimen in my possession, by Dr. Charles Heitzmann, of this city. The eighth and ninth dorsal vertebræ are only slightly invaded. About one-half of the body of the tenth dorsal (C) and first lumbar (below A) vertebræ remain, while only a small remnant (R) of the body of the eleventh dorsal is to be seen. No trace of the body of the twelfth dorsal exists, it having been entirely destroyed by the carious inflammation. An abscess cavity, though it contained but little pus (A), occupies the site of the former vertebral bodies. The membranes of the cord and the adjacent periosteum have become fused together (D) and serve as a lining to the abscess cavity.

These, then, are the terrible ravages of disease which the surgeon is sometimes obliged to face, and which, when the patient comes under treatment early in the disease, he seeks, through the agency of mechanical and other remedial measures, to aid nature in preventing. Owing to the inaccessibleness of the diseased areas of bone, they being buried deeply beneath the soft parts, it would at first sight seem as if the surgeon were powerless to aid nature in such a manner that the vital forces, as manifested by the disastrous metamorphoses of disease, would finally become so transformed as to establish physiological action. Such a transformation would constitute the cure of the disease, and is therefore the ultimate aim of all our therapeutic endeavors.

Now, let us see how we can approach this problem in a rational manner from the standpoint of existing knowledge. At the outset it should be understood that in ostitis or caries of the vertebral bodies, the establishment and consummation of reparative processes, such as have been indicated, depend upon the material lessening and final arrest of irritation.

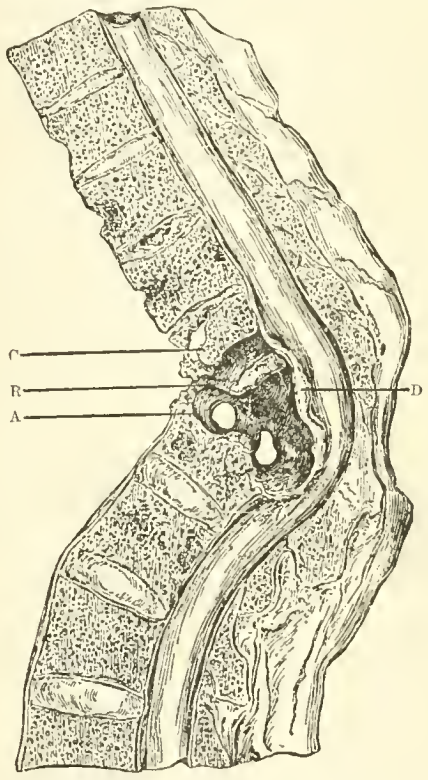

FIG. 1.

But how are we to lessen and finally arrest irritation? Before we can answer this question intelligently, it will be necessary to first formulate the sources of irritation. The irritation which it is in our power to lessen or remove is:

First, that which is caused by undue pressure at the seat of disease from superimposed bodily weight.

Second, that which results from the traumatisms of locomotion; or, in other words, the vibratory impulses which are due to the impact of the feet against the ground, and which are imparted to, and conducted up, along the bony framework to the seat of disease.[1]

Third, that which results from riding in vehicles of any kind—again, jars or vibratory impulses which are transmitted along the bony framework to the seat of disease.

The relief of irritation from the first-named cause, viz., superimposed weight, involves the use of an apparatus which will either transfer the weight of the parts of the body above the seat of disease to healthy parts below, or to some source of support other than the body of the pa-

[1] The Fundamental Principles of Mechanico-therapy in Hip Disease; based on a Consideration of Clinical, Pathological, and Physico-Physiological Data, with a Description of New Forms of Elastic Tension Hip Splints. Read before the Medical Society of the State of New York, February 6, 1884. The New York Medical Journal, March 15, May 3, and May 24, 1884. Proceedings of the Medical Society of the State of New York, 1885.

tient. Just how this is to be accomplished, how and where to get hold of the body, will be fully considered later on.

The relief of irritation from the second and third named causes, viz., jars or vibratory impulses, involves, in addition to the thorough sustentation of the patient, the use of an apparatus which will at the same time interfere with the transmission of jars or vibratory impulses along the bony framework of the body to the seat of disease. It will therefore be seen that all forms of rigid support, such as the plaster jacket and various forms of rigid apparatus made of iron or steel, do not, and cannot, meet these indications. An elastic or resilient apparatus is required.

But how is the relief of irritation to aid repair? It is all-important, for every surgeon who assumes the responsibility of treating the afflicted, that he should be able to give a rational answer to this question. The answer is this: In all inflammatory lesions of bone we have the formation of new embryonic cells. Now, if the irritation be excessive, these cells will break down and form waste products; if, however, the irritation be not too great, they become developed into healthy bone-tissue.

Thus, in the first place, it will be seen that, *for the cure of disease*, we have a clear indication for the relief of mechanical irritation by means of mechanical appliances; and just in proportion to the thoroughness with which we are practically able to carry out this indication, will reparative processes be established.

In the second place, *for the relief of suffering*, the complete and permanent removal of superimposed bodily weight will be found all that is necessary to overcome the pain resulting from pressure upon the sensory nerves.

In the third place, *for the prevention of deformity*, no success will attend treatment unless the vertebral bodies are kept from falling together by the removal of superimposed bodily weight.

In illustration of the beneficial results which accrue from affording thorough sustentation to patients affected with spinal disease, and in preventing jars or vibratory impulses from reaching the diseased areas, I may cite the case of a patient suffering from cervical caries, who was sent to me for treatment by Professor William C. Jarvis, of this city, June 27, 1881.

Fig. 2.

Fig. 3.

The disease had advanced to a condition in which it was absolutely impossible for the patient to maintain his head erect. It fell forward so that his chin rested upon the sternum, except when he supported it, as shown in Figs. 2 and 3. The method of supporting the head with the hands, illustrated in the figures referred to, was the one resorted to by the patient almost continually during his waking hours. By the application of an apparatus such as is illustrated in Fig. 4, the head was restored to, and maintained in, its normal position, thereby relieving the diseased areas from undue pressure. Jars or vibratory impulses were prevented from reaching the diseased vertebral bodies by means of two strong, spiral springs playing upon upright steel rods, which were placed upon either side of the neck, and so arranged as to exert linear traction upon the neck by tending to increase the distance between the upper or cervico-cephalic, and lower or cervico-truncal encasements. In this manner the mechanical irritation was relieved, the local circulation restored, and reparative processes estab-

Fig. 4.

Fig. 5.

lished, so that, within a year's time, the patient was discharged, cured, with perfect mobility of the segments of the cervical vertebræ, and without deformity, as shown in Fig. 5.

Again, even after the morbid process has ceased altogether, there may still remain the indication for support, not for the arrest of disease, but for the relief of discomfort or actual suffering due to the cramping of visceral organs. This is always apt to be true in those cases where the disease has progressed so far as to seriously deform the spine, and thus, by interference with its normal linear contour, impair its supporting capacity. Fig. 6, from a photograph by Mr. O. G. Mason, of a man forty-seven years of age, who came under my observation November 25, 1882, is a good illustration of this class of cases.

Lateral curvature.—In lateral curvature, a potent factor in increasing the deformity and consequent pressure upon nerves is the overtaxing of the spine by superimposed weight. In support of this statement it is only necessary to recall the familiar experiment of making linear traction upon the spine for the temporary reduction or obliteration of deformity and relief from pain, for in this way we relieve the spine of its undue burden. A good idea of the effect of suspension or linear traction applied to the spine may be gained by a comparison of Fig. 7 with Fig. 8, which are photographs, by Mason, of the same patient before and during suspension. It should be borne in mind that no such effect as this can be produced by any form of apparatus which seeks to reduce the deformity by means of leverage. It is essential to remove super-imposed weight, and this fact should always be borne in mind when selecting an apparatus to be worn by patients thus afflicted. This statement will receive further reinforcement later on.

Spinal weakness.—In simple weakness of the spine, unaccompanied by deformity, the patient continually as-

sumes faulty attitudes, especially in sitting, thereby cramping the visceral organs and giving rise to consequent discomfort. All such patients are greatly benefited by using a stay that precludes the possibility of their getting into these faulty attitudes.

These, then, are the considerations which lead us to make use of mechanical supports in the treatment of spinal affections. The therapeutic problem, therefore,

Fig. 6.

resolves itself into two questions: First, as to how and where to get hold of the body in order to support it in such a manner as to relieve irritation, by preventing the weakened or diseased member from being over-burdened; and secondly, the determination of the best means or therapeutic agents to employ in order to effect this most desirable end. In the present communication I shall deal only with the first question. A rational idea of this subject will be gained by considering the

Orthopragmatic[1] *holds of the body.*—In considering how and where to get hold of the body in order to support it, the body should be viewed from a thoroughly mechanical standpoint. We have the skeleton and overlying soft parts to deal with. Now, it is the prime function of bone to support weight. If, then, we are to transfer the weight of the parts above to a point below in order to relieve an intermediate diseased segment of the spine from mechanical irritation, it must be accomplished by getting hold of some part of the skeleton above and below the diseased zone, and introducing some form of artificial prop to take off the burden from the weakened spine. A clear idea of this extremely important part of our subject may be gained from a consideration of the normal relationship of the different parts of the body. Fig. 9 is a diagrammatic representation of a posterior view of the skeleton of the head and trunk, together with overlying soft parts, which I have elaborated as a result of my efforts as a teacher to illustrate this subject.

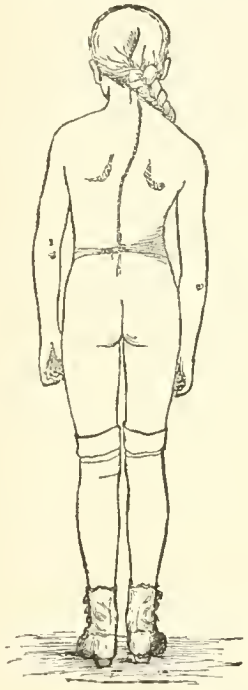

Fig. 7.

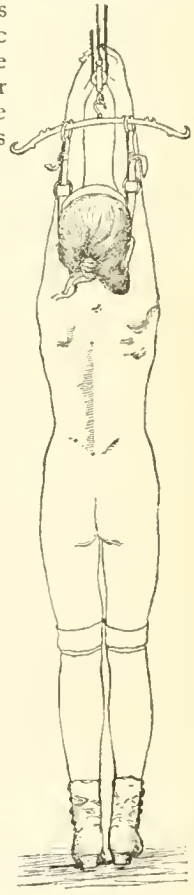

Fig. 8.

First, let us consider what parts of the skeleton we can utilize for getting hold of the body so as to relieve a diseased segment of the cervical spine, as at C. Before we go any further I wish to call attention to the fact that it is sound mechanical practice to secure a basis of support as near to, and directly under, the object to be supported as possible. Keeping this fact in mind, let us examine the skeleton as shown in Fig. 9. It will be seen that directly beneath the diseased zone C, we have that strong osseous structure, the shoulder-girdle. When we recall to mind the enormous loads which are habitually carried by laboring-men on this girdle, we are not inclined to look farther for a basis upon which to rest our support—it is both strong and near at hand. The dotted lines *b*, Fig. 9, indicates the extent of the surface available upon which to rest the shoulder-girdle envelope. Just above the diseased zone C, we have the globular form of the skull presenting, together with the lower jaw, as conve-

[1] Robert Heather Bigg, in his book entitled, Orthopragms of the Spine, London, 1880, page 56, remarks as follows in explanation of the meaning of the word "Orthopragm." "The human body has been shown to be a magnificently constructed machine. Under ordinary and natural circumstances its formation is mathematically perfect, its material strength and motor powers entirely adequate to its wants, and its integrity unimpaired. Under extraordinary ones, its symmetrical accuracy becomes lost or lapses into distortion, its inhereot abilities diminished, and its members abortive or accidentally removed. The human machine, in short, becomes in some point defective, and in these conditions a complementary mechanism or 'orthopragm' is adapted to make good the deficiency."

nient bony prominences, against which points we can make upward pressure or linear traction. This may be accomplished by adapting an occipito-mental encasement to the overlying soft parts (see dotted lines *a*, Fig. 9); and extending between this and the shoulder-girdle envelope on either side, adjustable bars (*a'*, Fig. 9), by means of which the weight of the head can be transferred directly through the lateral bars to the envelope adapted to and resting upon the shoulder-girdle, thus relieving the carious cervical spine of mechanical irrita-

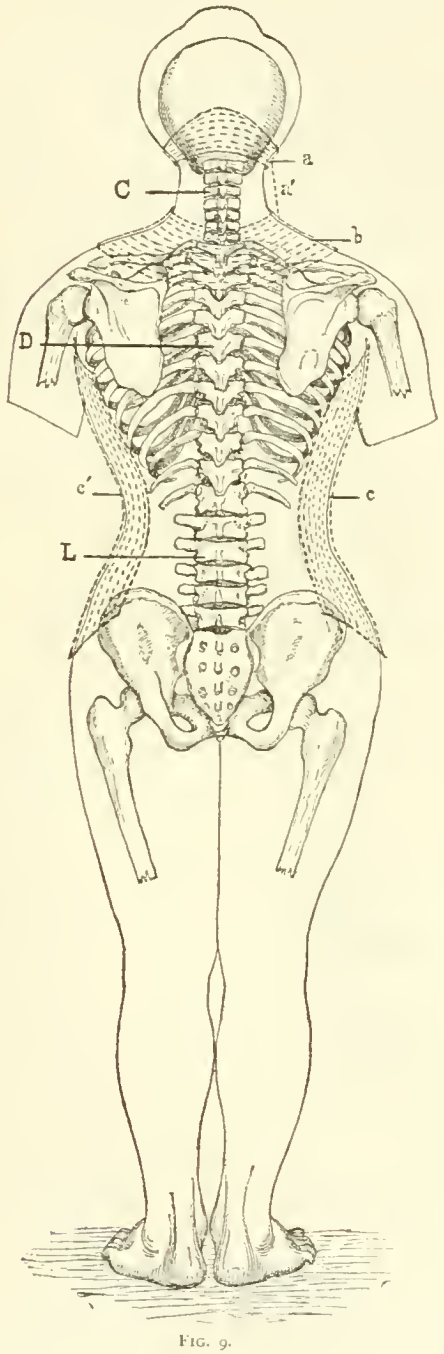

FIG. 9.

tion and undue burden. An appliance which I have invented for this purpose has already been alluded to (see Fig. 4).

Second, as to what parts of the skeleton we can utilize for orthopragmatic holds when the dorsal region of the spine is invaded as at D. Again examining the skeleton, we see that there is no bony prominence immediately below or above the affected zone which we can utilize for this purpose. Proceeding from above downward in search of a place upon which we can rest our orthopragm, the first site which presents, is, that of the pelvic girdle Here it is quite evident that we can get a very satisfactory hold of the body. Surveying the skeleton upward from the diseased zone, we find no bony prominences which can be utilized to get hold of the body so as to exert force to transfer the weight of parts above D to the pelvic girdle, until we again reach the globular form of the skull at *a*. It will thus be seen that, when we come to attach appliances to the body for the support of patients affected with disease of the dorsal vertebræ, we are working at a much greater mechanical disadvantage than when dealing with the problem of relieving mechanical irritation in the cervical region. One great disadvantage which we labor under is the enormous weight of the head, shoulders, upper extremities, and that part of the body above the diseased vertebræ at D which must be transferred by means of the occipito-mental encasement to parts below, in order to relieve the irritation at D.

The fact should not be lost sight of, that the head presents an extremely small area which can be utilized for orthopragmatic purposes, in transferring, through the agency of the applied support, this enormous weight, already referred to, to the pelvic girdle.

Finally, as to the relief of mechanical irritation when the lumbar vertebræ are involved, as at L:

Inspecting the skeleton with reference to orthopragmatic holds, we again find ourselves fortunately circumstanced. Here, as in the cervical region, we have bony prominences both immediately below and above the diseased zone, which can be utilized for applying a support to the body in such a manner as will transfer the great weight above the point L to the pelvic girdle. I refer of course to the bulge of the thorax above and, to the pelvic girdle below. The dotted lines, *c*, *c'*, indicate the position of orthopragms applied to the body for the transferring of the weight of parts above, to the girdle below.

It is a pertinent fact, and one that should never be lost sight of by those who are brought into the responsible position of making a prognosis, in any given case of spinal caries, regarding the prevention or arrest of the development of deformity, that the results of treatment in the vast majority of cases tally exactly with the above ideas regarding mechanical support of the spine. That is to say, the best results are obtained when the cervical and lumbar regions are affected; the most disastrous when the middle dorsal region is the seat of disease. Formerly, it was supposed that in the mid-dorsal region the best results could be obtained by treatment. Regarding the diseased and deformed spine as a broken shaft which could be drawn into position by means of a lever, theory suggested the idea that, with a fulcrum in the middle of the back and power applied to the body above and below, deformity could be prevented or overcome by drawing the body backward above and below against the lever, where it could be secured. But it must be remembered that the spinal column cannot be likened unto a shaft broken at one point—it has many segments—and that to execute the above idea in the same way that we would reduce deformity when a long bone is fractured in its middle is out of the question.

It will be understood, from what has already been said, that the problem of selecting orthopragmatic holds for the purpose of relieving diseased vertebræ of irritation, or the spine of its undue burden, is by no means always as simple as it would at first appear. It will be remembered that we have been considering this subject with reference to the normal relationship of the parts. Now, when patients come to us for treatment, these normal relationships are frequently found changed. The ground gone over is of great practical service, however; for in these days of diagnostic skill, patients with spinal caries are not infrequently brought under treatment long before the normal relationships of the skeleton have been seriously changed, or, in other words, before deformity has developed. Not only is this true of caries of the spine, but the same may be said of the early detection of lateral curvature. Then, again, there is a third reason why

the ground gone over is of great practical service. There is no inconsiderable number of patients who require mechanical support, not for the relief of spinal deformity or vertebral disease, but in consequence of spinal weakness.

When, however, we come to deal with patients requiring support, in whom the disease has already advanced so far as to give rise to serious distortion of the bony framework, the question of selecting orthopragmatic holds not infrequently becomes a difficult problem to practically solve. Take, for instance, individuals who are seriously deformed, as the one represented in Fig. 7. Under such circumstances it will be found that the lower ribs project down into the pelvic brim, and almost preclude the possibility of getting hold of the pelvic girdle and parts above so as to exert force advantageously. The reason of this is that the normal variations in the circumference of the pelvis, the waist, and thorax no longer exist. Not infrequently the waist measurement, or the measurement at the point which ordinarily corresponds to the waist, exceeds by a number of inches the circumferential measurement of the pelvis, while the circumference of the thorax on a level with the armpits is also less than that of the waist. When these abnormal changes in the circumferential measurements at the three points above named are due to changes in the relationship of the parts of the bony framework, it is a mechanical impossibility to get hold of the body with any portable support in such a manner as to effectually relieve all irritation. Enough support may be rendered, however, to add greatly to the comfort of the patient. Under such circumstances, if the disease be active, we should not permit either ourselves or our patients to rest contented with even the best of portable supports. Certain adjuvants should be made use of to bear the superimposed bodily weight. Of adjuvants of this class I have invented the suspension tricycle and the suspension crane, attached to the casement of a door or window or chair in which the invalid sits; and finally, a car travelling on a track attached to the ceiling. Having applied a portable support to the class of patients now under consideration, and provided it with shoulder- and head-straps, if necessary, the additional weight which it is desired to remove from the spine is transferred to one of the above-named mechanical adjuvants.

Sometimes the waist measurement of the patient exceeds that of the pelvis and thorax, the cause not being due to changes in the skeleton. This is especially apt to be the case in early caries of the spine affecting very young children. In such subjects the large waist and projecting abdomen are for the most part due to distention of the large intestines with gas, intestinal disturbances being a frequent occurrence in this class of cases. Under such circumstances it is possible to make sufficient circumferential compression at the waist to overcome the difficulty.

105 Madison Avenue.

For Vomiting of Pregnancy.—Professor H. C. Grosvenor (homœopath) says: "My usual treatment is sulphate of hydrastia, dissolved in water, sufficient to give the water a straw color. To be taken *ad lib.* If heartburn accompanies the nausea, put salycilic acid in the same glass. For pyrosis use Apollinaris water. When nausea is very severe two grains of svapina [a preparation of opium] in half a glass of water is to be taken in teaspoonful doses." Professor John W. Streeter [homœopath] spoke upon the same paper as follows: "I have had some unmanageable cases. My best remedy is chicken's gizzard [ingluvin], ten grains, as often as necessary. My second best remedy is skunk cabbage, 4oox. Look out for some local cause. Examine the pelvic organs." It will be seen that the above professors recommend only one homœopathic remedy, viz., skunk cabbage.

MENSTRUATION, ITS NERVE-ORIGIN—NOT A SHEDDING OF MUCOUS MEMBRANE.

By James Oliver, M.B., F.R.S. Edin.,

Member of the Royal College of Physicians, Assistant Physician to the Hospital for Women, and Honorary Physician to the Farringdon General Dispensary, London, England.

In every healthy human female, during the so-called childbearing epoch, which extends, on the average, over a period of thirty-two years, the uterus becomes the seat of a periodically recurring functional disturbance, evidenced by the emission of a more or less marked hemorrhagic discharge. As the initial establishment and each subsequent recurrence of this monthly phenomenon is frequently accompanied by symptoms of a general as well as local character, we shall designate under the appellation *menstruation* the whole essential train of events, and not its mere outward manifestation.

The molecular world, organic as well as inorganic, exists in a perpetual state of trepidation, and equilibration of a vital character is the outcome of an inherent power of adaptation. Normally the structural and functional integrity of the organism is maintained by a mutual dependence of the organs upon each other, and according to the manner in which these, each and all, respond to those multifarious changes which, from time to time, arise in the environments of the individual. The variations in the waves of molecular motion occurring in every organ, and associated with physiological activity, are radiated to, and affect, however feebly, every ultimate tissue of the body. So completely is this intercommunication, through the medium of the nervous system, carried on, and so apt are the different structures of the organism to perform functions other than those for which they have apparently become specialized, that vicarious compensation may be readily established. In the case of double organs it is a noteworthy fact, with which everyone is familiar, that the removal of one may affect but little, if at all, the well-being of the body; generally the remaining organ at the same time becomes of augmented functional activity, undergoing slight or even well-marked enlargement. This compensatory change will be manifested, not only by organs recognized as active, but also by such as have hitherto been viewed as obsolete. In many of the lower organisms, where structural differentiation is ill defined, vicarious function is readily fulfilled. The animal may, for example, be turned outside in with impunity, the vital integrity of the organism being still maintained unimpaired—the endoderm, already but feebly specialized, although set apart for assimilation, performing with ease the function of the ectoderm, that of elimination; while the ectoderm, in turn, assumes forthwith the power of assimilation, and discharges effectually a function hitherto foreign to it and performed previously by the inner layer. In the animal economy we see constantly enunciated the fact, too frequently ignored, that functional activity and structural integrity proceed together, hand in hand, and are regulated by a mutual action and reaction upon each other.

If the functional activity of any organ be augmented, but not unduly, the structural integrity will be maintained and be rendered more perfect. Again, the more complete the structural arrangement has become, the more likely we are to find the function actively performed. All visceral activities are now, through habituation, fulfilled in a somewhat automatic manner; and although these transitional states may at one time have excited a conscious sensation, they are at the present stage of evolution wholly ignored by the higher cells of the cerebral lobes which participate in feeling. What is true of one organ of the body is likewise true of all the others. It is, therefore, more than probable that the physiological changes recurring from time to time in the uterus are anticipated by, and in reality the sequence of, a molecular disturbance arising spontaneously in some centre located in the higher part of the cerebro-spinal tract, possibly

somewhere in the medulla oblongata. The mere fact that the functions of the uterus may be revealed uninterruptedly after the spinal cord has been completely severed in the dorsal region is no criterion, and cannot justify us in concluding that there exists no representative higher centre. Structural evolution itself forbids the acceptance of such an hypothesis. Like all other nerve-centres fulfilling a similar dispensation, this uterine centre is undoubtedly beyond all volitional control, but is, nevertheless, capable of being disordered by emotional impressions. With this fact everyone is familiar. A sudden shock experienced during menstruation, and apart from any bodily injury, will produce, as I have frequently noted in some females, immediate cessation of the flow, and even interrupt for a more or less indefinite length of time thereafter its amount and periodic regularity. The resulting disturbance will depend essentially upon the state of the nervous system and its proneness to molecular instability.

With the approach and appearance of the monthly flow the whole frame, as one would naturally expect, participates more or less in the change, and the amount of disturbance experienced, as well as manifested, is commensurate with the power the organism possesses of adaptation, and hence of equilibration. The simple determination of blood, because of increased functional activity, to the genital and, in many cases, to the other pelvic organs of itself produces a definite alteration in the waves of molecular motion proceeding therefrom, and which, radiated in all directions, must necessarily affect the vascular state of other very important structures. In many chronic disorders, of whatever system, affecting the female, every observer must have remarked that, according to the menstrual type of the individual, there is often, either in anticipation or with the appearance of the flow, a proneness to aggravation, or in some very exceptional cases, it may be, to alleviation of symptoms; and with the cessation or disappearance a corresponding gradual reversion to the original already stationary or slowly progressive state. In some few cases the loss of blood may account for much of the disturbance manifested, yet it cannot be the sole factor. In many women, where, from some inexplicable cause, there is for a more or less indefinite period a total suppression of the characteristic discharge, we may detect frequently such a regularly recurring alteration in the symptoms or manner of the patient as to place beyond denial a direct relationship. In no class of functional disorder do we find so regularly and markedly an interference with the outward manifestation of uterine activity as in *epilepsy*, a disease the pathology of which is still undetermined. It is more than probable, however, that as we may consider the *epileptic female* as *epileptic* throughout, even to the finger-tips, the interruption of the periodically recurring functional change in the uterus is the result of some occult condition of the corpuscular elements governing the activity of this organ, and wholly independent of any defective structural state of the viscus itself. The structural integrity of the uterus may, however, eventually suffer, for inaction and overaction alike tend to exert a prejudicial influence.

Gestation, as a rule, although not invariably, determines for a period of nine months a cessation of the monthly recurring flow. Not infrequently, however, we see women who throughout one or more pregnancies continue perfectly regular, the amount or character of the flow being unaltered by the physiological process going on in the uterus. Usually the fertilized ovum affects in some unknown manner the uterine organ, thereafter destined to be its source of nutrition, and the gradual molecular variations so produced are radiated to the uterine centre, alter the corpuscular state, and determine the sequence of events. During the period of lactation, and consequent activity of the mammary glands, we find not only the manifestation of the monthly recurring functional change of the uterus held in abeyance, but also the activity of the generative glands, as impregnation rarely occurs while the mother continues to suckle the offspring. Should, however, lactation be prolonged indefinitely, the secretion of milk may become more or less habitual, as in the case of the cow, and the generative glands regain their activity. The life of every organism is twofold: first, the maintenance of the individual, and then the perpetuation of the species. The latter, however, is always subservient to the former, and so long as there exists a demand for nourishment from the mother on the part of the child in utero, so long will the reproductive power, as a rule, continue latent. Occasionally, however, I have noted that while the child is being suckled by the mother the uterus itself, and the generative glands, may throughout continue active; and impregnation resulting, signs of early constitutional enfeeblement are apt to accrue. In inflammation of the mucous lining of the Fallopian tubes with puro-fibrinous exudation, menorrhagia is frequently an associated symptom, and apparently results from some interference with the nerve-supply to the uterus. In all mammals there are two ovaries, and the oviducts are known as the Fallopian tubes. Each oviduct dilates, on its way to the external surface, into an uterine cavity, which in turn opens into the vagina. In the monkey and man only do we find the two uteri coalesce inferiorly, producing a single cavity, into the fundus of which the Fallopian tubes enter. It is more than likely that the nerves governing the functions of the uterus are transmitted along the Fallopian tubes, and although menstrual disorder may frequently result, with distinct pathological changes existing in these tubes, we must not too hastily conclude that these structures, *per se*, govern the uterine changes.

The true nature of the catamenial discharge is still conjectural; yet its elimination from the body renders it highly probable that, having already served some special end, its detention in the blood may exert some deleterious influence on the animal economy.

It is generally admitted that ovulation and menstruation are coincident; that they may or may not be, I am not prepared to dispute; that, however, they are invariably associated there seems to me much reason for doubt. That the discharge of an ovum may, and frequently does, occur quite independently of menstruation, I have no misgivings. No one would entertain the idea of gauging the reproductive power of the female either from the regularity or amount of the catamenial discharge. I have occasionally noted that women who menstruate with marked irregularity are specially prolific.

It is alleged as an established theorem, that from the period of puberty to the climacteric age there is, besides a gradual death of the mucous membrane lining the whole uterine cavity—which must ever occur to be compatible with life—a more or less regularly recurring and complete death of this coat. In the whole animal kingdom we search in vain for a physiological change truly analogous with this. The serpent, it is true, may shed its skin more or less intact; but ere it casts off the old coat a new one is already regenerated to protect its body from all extraneous injurious influences. In vital structures change is wont to be gradual—creation and destruction proceed together. There is apparently no departure from this inexorable law. Death of the mucous lining of the uterus takes place imperceptibly; the change is one ever going on, as in all organs of the body.

In several cases I have examined uteri removed from women who have died, not only during menstruation, but just before an expected period. In two cases the death was sudden, the patient at the time being in apparent good health. In three cases the uterine organ was invaded by growths of a fibroid character, which were chiefly submucoid. To the naked eye the mucous lining, in all, appeared in every respect like that of a normal uterus examined at any time indiscriminately. In no case did I detect any breach in the continuity of the lining membrane of the uterus, except in those in which this organ had be-

come the seat of fibroid growths. In such the mucous lining had in places become markedly thinned, or even vanished altogether, because of a constant vital pressure exerted on this coat by the underlying new-growth. Here gradual absorption had resulted, very much in the same manner as bone and soft tissues disappear before the constant pressure of an increasing aneurism. I have never at any time detected any evidence of structural change, microscopically, in the inner linings of the uterus, in cases in which this organ has been removed from the bodies of females who have died either during or just before an expected menstruation. The glands which stud the inner coat of the uterus in its entirety, consisting of columnar cells, lined by a basement as well as a limiting membrane, have, however, shown marked enlargement, in many cases so pronounced that the outline, not only of the separate cells but even of the gland itself, has been lost. The columnar cells appear swollen, and contain frequently large corpuscular-looking bodies, which I believe to be the simple manifestation of increased functional activity. Prior to cutting, by freezing in gum the tissues had been hardened for two days in spirits, and finally in a weak solution of chromic acid. The sections I stained in a variety of ways, my best stain, however, and that affording clearest definition, being *iron* and *pyrogallic acid*.

Those who support the denudation theory assert that each recurring monthly flow is anticipated by a fatty degeneration of the mucous lining of the uterus; that blood is extravasated into its substance, and eventually the whole, becoming disintegrated, is washed away imperceptibly with the escaped blood. A new mucous membrane is thereafter by degrees regenerated from the inner layer of the muscular coat, which, in its turn, too, like its predecessor, must undergo a similar degenerative change, and ultimately be removed from the body. Some of the lower animals, it is true, retain the power of reproducing limbs, and possibly other parts of the body removed by accident. If, however, the separation of the part be too frequently practised, we eventually exhaust the power—wholly irrecoverable—the structural integrity of the regenerated limb or tissue becoming less and less marked with each removal. Clinically, if the mucous membrane were shed with each catamenial flow, it must be capable of completing its cycle of degeneration, shedding, and regeneration, in an incredible number of days. Many are the menstrual anomalies which preclude the acceptance of such a phenomenon.

Taking all the facts into consideration, it is more than probable that the recurring monthly discharge in the human female is a secretion, or rather excretion, from the inner lining of the uterus and Fallopian tubes, without degenerative change other than that commonly associated with augmented functional activity, and comparable with that occurring in any other organ of the body under similar circumstances.

THE DEMAND FOR PHYSIC.—It is all very well for Sir William Gull to treat his aristocratic patients, as he wishes the profession to believe he does treat them, by leaving them to their warm bed and nature's efforts. Many doctors would be delighted to have the same liberty of action, but Mrs. Jones round the corner believes in physic, and if her medical attendant thinks otherwise, *tant pis pour lui*. It is idle for Sir William to pretend that this deeply seated prejudice is due to many years of apothecary rule. It exists in climes where the apothecary has been unknown for a century or two, and it flourished before he existed as a genus. Indeed, the desire to take physic is natural enough, for its results in certain disorders and maladies are very marked and beneficial, and one can hardly expect a suffering public to distinguish clearly between the complaints which are, and those which are not, benefited by drugs.—*Hospital Gazette.*

TWO CASES OF COMPOUND GUNSHOT FRACTURE OF BOTH EXTREMITIES.

CONSERVATIVELY TREATED, WITH RECOVERY.

BY RICHARD COLE NEWTON, B.A., M.D.,

ASSISTANT SURGEON U. S. A., FORT ELLIOTT, TEX.

CASE I.—J. D——, a Mexican, aged forty-two, of robust physique and an excellent previous history, was received into the post-hospital at Fort Stanton, N. M., November 15, 1881. He had been engaged in an altercation on the previous day, and had received two gunshot wounds as follows: His assailant seized an ordinary Winchester repeating rifle (calibre, .44-inch) and fired at him at a distance of three or four yards. The patient fell down, and his cowardly adversary, standing almost directly over him, fired again and then fled.

The first bullet had passed through the lower portion of the left deltoid muscle, between the humerus and the skin. Its course had been backward, inward, and slightly downward. On emerging it had carried away a piece of the integument from the posterior axillary wall as large as a fifty-cent silver-piece. The humerus had not been struck by the bullet, as no bare bone could be detected by the finger or probe, but the bone was transversely fractured. The fragments were not displaced. The long head of the triceps was cut in two and the torn ends protruded, one from the upper part and one from the lower part of the wound of exit.

The second ball had passed through the right forearm, entering upon the radial side of the anterior aspect, three inches below the elbow-joint. It had emerged on the ulnar side of the posterior aspect, four inches below the elbow. About the wound of entrance one or two tags of torn muscle were hanging. A surface two and a half inches long by one and a half inch wide was denuded of integument. The wound of exit was more extensive. Three or four ruptured muscle-ends were protruding about the edges of the wound. The soft parts were bruised and pulpified, and fragments of bone were visible among the flesh. An area three inches wide and four inches long had been deprived of its integument and the underlying fatty and connective tissues.

Both radius and ulna were fractured and extensively comminuted. There was pulsation, however, in both radial and ulnar arteries, and the surface of the hand was not cold. There was slight power of movement in the thumb and one or two fingers. The swelling and deformity were considerable, and the forearm was considerably shortened.

The most probable explanation of this extensive wound is that the muzzle of the rifle, being only a few feet away, when discharged, from the arm, which was presumably resting upon the hard ground (the uncultivated soil of New Mexico is, as a rule, hard and gravelly), the tissues suffered from the following forces: (1) The direct impact of the ball; (2) the explosive force of the gases of combustion and of the unburned powder; (3) the bruising against the hard earth; and (4) the rebound of gravel-earth, etc., and possibly of the bullet itself.

Drainage-tubes were pulled through both wounds, which had been well washed with carbolized water. Small, light, straight wooden splints were applied. Dr. F. H. Atkins, U.S.A., and Mr. G. A. Mills, a dentist, from Brooklyn, N. Y., were present and assisted the writer with good counsel and in many ways.

The case gradually progressed to recovery, without a bad symptom. The left arm was apparently entirely well in eight weeks, without deformity or impairment of power. The superficial wound on the posterior axillary wall, which has been described as the loss of a bit of integument as large as a fifty-cent silver-piece, proved larger than we expected, and a slough the size of the palm of the hand came away, thus furnishing another evidence of the extensive bruising that occurs in gunshot wounds. The excavation granulated nicely, and

healed in about the same time as the wound of the left arm. On March 11, 1882, the writer turned over his charge as post-surgeon at Fort Stanton to Assistant Surgeon E. T. Comegys, U.S.A. The right forearm had then nearly healed up, but neither the fractured radius nor ulna had united. Bony fragments were from time to time discharged. On April 7th a letter from the hospital-steward said: "J. D—— still in hospital. No change. Pieces of bone coming away yet." On May 10th Dr. Comegys wrote: "J D—— left, because we objected to his getting drunk. Ulna reunited, but radius not."

Case II.—Private L——, Troop G, Fourth United States Cavalry, was brought into the field-hospital at Fort Cummings, N. M., on April 25, 1882. He had been wounded in "an affair with Indians" at Stein's Peak Pass, N. M., at about 4 P.M., April 23d. That same evening he rode eighteen miles on horseback. Most of the next day he and three wounded companions lay in the scorching sun, with one canteen (a little over a quart) of water between them. That afternoon they began a journey of forty miles, in a wagon, to the railroad. This they reached before daylight next morning. Thence sixty miles by rail (one soldier died in the cars) and six miles more by wagon, into Fort Cummings.[1]

Dr. W. Whitney, U.S.A., had charge of the party. L—— displayed great courage and patience. He was an American, aged thirty-five, of medium size and wiry build. His habits and family history were good, with no obtainable evidence of syphilitic taint. Two rifle-balls had struck the patient, as follows: The first had entered the arch of the left foot just below and anterior to the ankle-joint, in front of and about on a level with the outer malleolus; it had passed inward, slightly backward, and downward, and had emerged two inches below and a little anterior to the inner malleolus. The ankle-joint was not involved.

The second bullet had struck the right tibia on its internal face, at the junction of the upper and middle thirds, fracturing and splintering the bone. There was no wound of exit. The patient declared that the bullet had fallen out, and that it was a ricochet. The latter statement we were fain to accept, because the wound was oblong, irregular, and ragged. As to the former assertion we were sceptical, and spent a long time looking for the bullet. Dr. Gross has warned us that no reliance can be placed "upon the patient's assertion that the bullet has dropped out, unless the missile be found in his pocket."[2] Indeed, months afterward this bullet was searched for. The wound of the integuments was, as stated above, ragged in outline and irregular in form, and the surrounding tissues were bruised. A clot sealed the wound. But this was removed and the fractures of the tibia made out. The bony fragments were movable, but resisted moderate traction looking to their removal. A few blebs containing clear serum surrounded the orifice. The ecchymosis was considerable. The fibula was found not broken. There was moderate swelling and deformity. About four inches below the bullet-wound a sharp fragment of the tibia had nearly worked its way through the skin.

The leg was laid in a fracture-box filled with bran and kept wet with water, after having been well syringed with the same. To the foot similar applications were made.

Temperature, 100°. Pulse, about 100. Ordered quinine and supporting treatment, and carbolic acid was added to all the dressings. During the next four days the temperature ranged from 99¼° to 102¼°, and the pulse from 90 to 108.

April 29th.—The patient complains of pain in the leg, and of feeling sick, with headache and want of sleep. There is a putrid odor about the leg, which looks black and unfavorable. The little blebs above spoken of have, however, disappeared, after the evacuation of their contents with a needle. Both wounds were dressed with iodoform powder in excess. The powder was rubbed into the wounds with the finger. In four hours the temperature fell ⅖°, and the pulse 16 beats per minute, which is the more noticeable as the hour of observation was near that of the highest daily febrile movement.

April 30th.—Morning: Temperature, 100°; pulse, 80. 3 P.M.: Temperature, 101°; pulse, 84. 8 P.M.: Temperature, 99⅘°; pulse, not recorded. Patient complains of a sleepless night. The leg has given him no trouble, but gain in this quarter has been accompanied by discomfort in the other wound. The bandages had to come off the foot, which is swollen and angry looking. At 8 P.M. undoubted erysipelas was present here. All the iodoform was washed away, and a solution of borax (gr. xx. to aq. ℥ j.) was substituted. This change gave almost immediate relief.

May 1st.—Pulse and temperature normal. The record was discontinued. Back-wounds looking better. The improvement in the leg was most marked. No putridity anywhere noticeable. Healthy granulations appearing, etc. Foot still erysipelatous.

May 2d.—Carbolic salve to foot.

May 14th.—Leg improving. Foot seems about stationary. The wash-water refused to go through the wound for the first time to-day. Tissues about the wounds of exit and entrance are yet somewhat boggy. A small abscess, containing about two ounces of laudable pus, has been evacuated behind the internal malleolus. Applied iodoform to this wound as before.

May 18th.—The foot-wound has improved greatly. Put two straight wooden splints on the leg in place of the posterior felt one.

June 15th.—The tibia is now firmly united. The probe, however, detects some bare bone in this wound. The foot-wounds are closed up. The man can stand for a few minutes on his feet, but cannot walk.

August 2d.—He was transferred to Fort Bayard, N. M., his proper station.

November 16th.—The writer saw L——, in company with Dr. Whitney. Patient walks all over the post, uses a cane, and limps somewhat. The left ankle-joint is in normal condition; L——'s general appearance greatly improved. The doctor says that spiculæ of dead bone occasionally come away from the foot. There seems to be necrosed bone in both wounds, and the doctor thinks that the bullet is still embedded in the tibia.

December 8th.—Dr. Whitney writes: "All the dead bone was removed from the tibia. No bullet found. Operation-wound healing kindly. Surgeon's certificate of disability for L——'s discharge has been forwarded."[1]

I do not claim that there is anything wonderful in these cases, or that the results were brilliant. They have seemed worthy of being reported, because (1) such cases are apparently not frequent; (2) because they were treated with almost absolute conservatism; (3) the action of the iodoform seems interesting, and (4) because they offer another tribute to the glorious and health-giving climate of New Mexico.

I should like to add a few notes under each of the foregoing heads

(1) As to frequency of double or multiple gunshot wounds. "The Medical and Surgical History of the War of the Rebellion"[2] says: "It is impossible to give even a proximate estimate of the frequency of the cases in which several wounds were found in the same individual. The cases were classed with those injuries which seemed to be the gravest."

Macleod makes a similar statement[3] in his "Notes on the Surgery of the Crimean War."

[1] Mr. Longmore (Holmes' System of Surgery, vol. ii., p. 142) calls attention to the distances over which the wounded must be carried, and of the *mode* of carriage, as influencing the prognosis.

[2] System of Surgery, vol. i., p. 334. See also Holmes' Surgery, vol. ii., p. 144.

[1] The writer's thanks are due to Drs. Whitney and Atkins for various favors in connection with these cases.

[2] Part III., Surgical Vol., p. 868.

[3] Notes on Surgery of Crimean War, p. 272.

It would seem that both accuracy and convenience would be subserved by a correct classification of multiple injuries.[1]

In the volume of "Surgical Cases since the War,"[2] from 1866–71, 3,213 gunshot wounds are recorded, and 219 compound fractures. But no double or multiple gunshot wounds. Mr. Hornidge says[3] that fractures of two or more bones in separate parts of the body are comparatively rare, not more than one-third of one per cent. of all fractures.[4] Compound fractures (single) would seem comparatively frequent, as Dr. Stimson gives the percentum, according to Gurlt, as sixteen, counting all fractures of the limbs.[5] Perhaps an approximate estimate may be arrived at as follows: The whole number of amputations recorded in the "Medical and Surgical History of the War" is 29,980,[6] of which 172 only were double—something over one-half of one per cent. It is fair to assume that the proportion of cases of multiple wounds that enjoyed conservative treatment is no larger than the proportion of wounds of a single extremity that were not operated upon. Probably the number of those suffering from double or multiple gunshot wounds who died before they could receive attention is large compared to the number operated upon. But it would seem that multiple gunshot wounds of the extremities did not form over one per cent. of all gunshot wounds of the limbs in our war.

The paucity of records of such cases is astonishing. A search through the principal medical journals for the last eighteen years reveals but two cases of double compound fracture reported since the war, only one of which was a gunshot wound. These were apparently reported because they recovered under conservative treatment.[7] The first occurs in Braithwaite (July, 1870, p. 106). Fracture of both legs in railway accident, left comminuted and right compound comminuted; conservatively treated, with recovery. The other (*American Journal of the Medical Sciences*, April, 1874) was a double compound gunshot fracture of right thigh, conservatively treated, with recovery. Reported by Mr. Stewart.

My friend Dr. L. A. La Garde, U.S.A., reports a case of fracture of the right tibia by a pistol-ball which then buried itself in the left foot. This case prospered under conservative treatment, although to insure complete recovery an operation to remove dead bone, and perhaps the bullet from the foot, may have to be undertaken.

(2) As to the treatment and results, we know that all good authorities forbid amputation of the forearm for fractures complicated with lacerated and comminuted wounds when the principal blood-vessels and nerves are intact, and also in compound fractures of the leg, not involving a joint, whenever the great vessels and nerves have escaped, and especially when only one bone is broken. And, in a general way, it is fair to assume that the same rule holds good in such wounds when there is another fracture in some other part of the body. Dr. Stimson says,[8] "Dupuytren first called attention to the fact that while the danger of wounds and fractures is undoubtedly greater when they are numerous, yet it does not increase in direct proportion to their number. On the contrary, when there are several fractures each one runs a milder course in general than if it were single." Some remarkable recoveries after multiple wounds, which are to be found in "Guthrie's Commentaries," "Macleod's Notes," "The Medical and Surgical History of the War," etc., are only to be explained by this hypothesis. Of course, the introduction of "clean surgery," the use of antiseptics, and the improvements in therapeutics of every sort have changed the old surgical rules somewhat. And, as Dr. Stimson says,[1] "It is now the rule to save the limb where formerly it was the exception. The surgeon can advantageously wait in doubtful cases." Sir W. MacCormac strongly advocates[2] delay even in removing bony fragments from compound comminuted fractures. He speaks of one soldier in the American civil war who received a gunshot wound of the elbow-joint, and another in the knee, the second ball lodging in the cartilage, having nearly penetrated into the joint; and adds, sententiously, that fortunately the surgeon did not believe the man's statement that he had a ball in his knee, and the patient had good use of this knee for years afterward.

(3) In the matter of iodoform dressings, Dr. Michael has given an excellent summary of the present state of surgical opinion relative to this drug.[3] In this it is said that Von Mosetig, to whom the credit of introducing iodoform as a general wound-dressing is due, lays down the rule that traumatic erysipelas will not occur in wounds dressed with iodoform unless the wound-secretions are retained. In Case II. erysipelas occurred when the secretions were apparently not retained. The wound was thoroughly washed out, the wash-water readily passing through before the iodoform was applied, and again twice the next day. To the best of my recollection the discharge was not obstructed at any time by the iodoform. And yet the latter could not be kept to the wound on account of the local disturbance. A fortnight later it answered admirably, although no change in the wound had occurred, except that it had partly healed up and the wash-water would no longer go through it. Another reason for believing the erysipelas to be purely local, and therefore probably due to the iodoform, is that the man's general condition improved and his temperature diminished, *pari passu*, with the development of the erysipelas. When the latter was at its height the patient's temperature was less than 100° F.

Almost immediately after the removal of the iodoform the pain and swelling about the wound began to subside markedly. I have noticed no reported cases of local irritation or inflammation from iodoform, in the journals (although I have not taken the time to search thoroughly for such reports). I had a case at Fort Cummings, N. M., where iodoform was applied to a superficial burn of the dorsum of the hand, then partly healed, and had to be discontinued as it provoked ecthymatous eruption with considerable burning and pain. These are the only cases of local trouble from iodoform that have fallen under my notice, although, warned by them, in all cases where iodoform threatens to be too irritating, I dilute it with an equal part of flour or starch, which gives most satisfactory results. There is, of course, the possibility that the drug was not chemically pure. But I believe that it was.

(4) It would not be just to omit mention of the action of wounds in the climate of New Mexico, which is so dry, so equable, so mild and delightful. Numerous papers have of late appeared in the journals relative to Colorado and New Mexico as health-resorts, especially for phthisical patients.[4] The efficaciousness of the climate in lung complaints is well known, and its salubrity shown in the healing of wounds is, I believe, as great, although not perhaps so familiar to the profession.

There is a case of Mr. Lister's, mentioned in *Braithwaite's Retrospect* (January, 1868, p. 121), in which a boy, aged thirteen, sustained a fracture of the humerus, with extensive laceration and injury to the soft parts. The distinguished surgeon is represented as congratulating himself on saving this limb by the use of antisepsis,

[1] Although Mr. Longmore asserts that tables "afford little aid toward the prognosis of particular cases, each of which must be estimated according to its own particular features and circumstances" (Holmes, vol. ii., p. 142).

[3] Holmes' Syst. of Surg., vol. ii., p. 41.

[4] I take it for granted that this includes gunshot fractures.

[5] Treatise on Fractures, p. 60.

[6] Op. cit.

[7] Some remarkable cases which had occurred during the war were given in THE MEDICAL RECORD. One (vol. xi., 1876, p. 14), reported by Dr. Beck, recovered after seven serious musket-ball and canister wounds, both femora having been fractured and comminuted. Another (November 3, 1883, p. 478) interesting case is related by Sir W. MacCormac.

whereas it would certainly have been amputated without them. In New Mexico we should expect to save the arm, in a similar case, *without* carbolic acid. In Case I., reported, carbolized washes were used, but no attempt at thorough antisepsis was made. (Nor in this case was iodoform used, at least for the first four months.)

The beneficial action of the climate of New Mexico, upon consumption and wounds alike, might be construed as supporting the theory of the local origin [1] of phthisis.

At all events, wounded surfaces and diseased lungs enjoy a remarkable opportunity to recover in the localities mentioned; and I think one writer has asserted that no case of pulmonary consumption has ever originated in Colorado.

THE INTRA-PULMONARY TREATMENT OF PHTHISIS PULMONALIS NEARLY ONE CENTURY AGO.

By JOHN B. RICHARDSON, M.D.,

LOUISVILLE, KY.

In searching through my library for the advances made in the treatment of phthisis pulmonalis, and comparing the modes of treating this affection during the last century, I happened upon a work, bearing date "Edinburgh, Scotland, 1796," entitled "Annals of Medicine, for the Year 1796," by Andrew Duncan, Senior and Junior, Fellows of the Royal College of Physicians, Edinburgh. This book was purchased by my father, the late Dr. Samuel B. Richardson, of this city, "in the year 1825."

The preface reads: "Twenty volumes of a periodical work, under the name of Medical Commentaries, have been published at Edinburgh by Dr. Duncan, Senior. It was chiefly intended to exhibit a concise view of the latest and most important discoveries in medicine and medical philosophy, particularly those which tended to improve the practice of the healing art. . . . They also hope, that reflecting practitioners will occasionally use this work as a channel for communicating to the public those practical observations which they think worthy of its notice. These may be transmitted either to Dr. Duncan at Edinburgh or to Dr. G. Pearson, Leicester Square, London. . . . In the present volume, the intelligent reader will find many things well meriting careful examination. Not to mention other particulars, if what is related respecting the effects of Nitrous Acid as observed by Dr. Carmichael Smyth, Mr. Patterson and Mr. Scott, shall be fully confirmed by the experience of others, the discoveries of the present period will be entitled to particular notice in the history of medicine."

This book contains (to us of the present day) many quaint ideas, some of which are considered *novel* means, even by the practitioner of the year 1887—*e.g.*, the *topical* use of remedies in phthisis pulmonalis.

An analogous instance, the supposed newly discovered disease (twenty-five years ago) "trichinosis," and its cause, the eating of diseased swine-flesh. Now, it is known that the Egyptians, Ethiopians, and Israelites, from the earliest ages, refused to eat the flesh of swine.

The Western nations departed from this rule, and in these modern days we are beginning to realize the dangers of this article of food, on account of the trichinæ contained in it; and when we turn to the Talmud, we are told that it was forbidden to the Jews "because of a small insect which infests it." Just in this connection it will be of interest to mention—as it is not, I believe, generally known—that "the Egyptians, the Ethiopians, the Phœnicians, and other ancient nations practised circumcision, not only as a religious duty, but with the view—which was attained—of stamping out syphilis, and it was not until Columbus reopened communication with the infected people of the West India Islands that the scourge crossed the Atlantic and 'turned Europe'—as one has expressed it—'into a charnel-house.'"

The above fact sets at rest the charge that America sent this disease to Europe, as has been accredited to be true. I copy verbatim the following from this work: "Dr. Girtanner's Observations on Consumption.—The writings of Dr. Beddoes, and the hopes of giving relief in this dreadful disease, induced Dr. Girtanner to make similar experiments, especially as he is not satisfied with the practical part of Dr. Beddoes's work, because attention was not paid to the different species of consumption, to the stage or cause of the disease; because the histories of the cases were not sufficiently accurate, and because the carbonic acid, azotic, and hydrogen gases were indiscriminately recommended.

"To proceed methodically, he resolved to make a series of experiments with one kind of gas, and he selected the carbonic acid gas, because it is specifically heavier than the atmosphere, and will therefore sink to the bottom of the lungs, so as not to be immediately expired again; because it has been found, by the experiments of Ingenhouss and Beddoes, to diminish pain, and promote the healing of wounds; because it is easily prepared without expense or fire; and lastly, because the use of hydrogen gas is attended with danger, if expired near a candle, from its conversion into hydro-carbonous gas.

"On April 3, 1795, Professor Hoffman carried Dr. Girtanner to see a student of twenty-three years of age, with whom he wished the new method tried. The patient lay upon a sofa, unable to raise himself up; his countenance was fallen, his whole body extremely emaciated, his tongue of a bright-red colour, his hands burning hot, his pulse 120 in a minute, and his voice hoarse and weak. He complained of violent cough, which deprived him of sleep all the night and troubled him much through the day. His expectoration was copious, tough, thick, and of a sulphur colour. During the night he sweated so much that he said he felt as if he lay in water. He had also a violent colliquative diarrhœa and occasionally bleeding at the nose, which was difficult to stop.

"Upon inspiring deeply, he felt severe pain in the right lung. He was first affected a year and a half before, after cold, and was daily growing worse, though he had followed the advice of the most celebrated physicians of Goettingen, who had now given him over. In the evening Dr. Girtanner made him breathe a mixture of one quart of carbonic gas and two quarts of atmospheric air. After lying a few seconds without motion, he said he felt as if relieved of a weight which till now had pressed him; he could breathe more freely, and he felt in the right lung a soft warmth and a pleasant tickling. In a quarter of an hour he breathed a second portion, and in half an hour the third. He was ordered to live upon smoked and salted meat, abstaining from all vegetables, and to drink water and beer but no wine. No other medicines were prescribed. . . .

"Till the 7th of May he breathed three portions of the above-mentioned mixture twice a day. Afterward it was increased to four portions each time. Until the beginning of May he continued to recover; his appetite returned; he slept tolerably quietly the greatest part of the night, and without much coughing; his expectoration was diminished and less yellow; the bleeding at the nose had not returned; the hectic fever was slight, and lasted but a few hours; he was less emaciated, and could walk about his room and amuse himself. His pulse alone was not better. It was still small and beat 120 to 130 in a minute. . . . On the 3d of July he was permitted to return to his common diet, as he was tired of salted meat, and complained that it made him cough. . . . About the middle of August his cough ceased, his pulse was soft, and beat 70 to 80 in a minute; he gained strength and appetite, slept well, and complained of nothing except a trifling cough. On the 27th of August he found himself strong enough to leave Goettingen, and to undertake a journey of about eighty miles on foot,

[1] Vide Dr. A. Flint's paper on The Bacillus Tuberculosis, Med. News, January 19, 1884.

which he performed, and is now, Dr. Girtanner has heard, very well.

"The conclusion to which Dr. Girtanner arrives from this and many other cases is that the respiration of carbonic-acid gas is a very active remedy, which in some cases is of great service, is of no use in others, and is even hurtful sometimes.

"Dr. Girtanner promises to take another opportunity of relating his trials with azotic and hydrogen gases, both of which seem to have a much more beneficial action than carbonic gas."

This book contains the article from the pen of Dr. W. Scott, of Bombay, on the "Effects of Nitrous Acid on the Human Body," extracted from the "*Bombay Courier*, April 30, 1796," with a description of his manner of preparing it, and its uses as a medicinal agent in the fevers of India and syphilis; also a letter from Dr. W. Scott to Sir Joseph Banks, which ends as follows: "I have no objection to my name being used on this subject, for I really believe that such a remedy would be highly useful to mankind, if judiciously employed, especially in warm climates, where a tendency to animalization gives a particular character to all diseases."

It also contains an article, "Zoonomia; or, the Laws of Organic Life," by Erasmus Darwin, M.D., F.R.S., author of the "Botanic Garden." I judge he was the father of Professor Darwin, of "Darwinism" reputation.

Clinical Department.

A SIMPLE METHOD OF PREPARING TAMPONS.

Dr. N. W. Cady, of Logansport, Ind., writes: "Some time since I hit upon a handy method of preparing tampons. When made in the ordinary way, tampons are usually not firm enough, and the knots tied in the retaining string often produce pain, or even slight ulceration. The implement which I use in preparing them is a bit of wire twelve inches long, ending in a loop or hook. A piece of strong linen thread is doubled, and then looped over the hook, the ends being secured at the other end of the wire by two or three half-hitches. Cotton, oakum, jute, or wool, is now wound firmly around the wire and thread until the roll is from four to five and one-half inches long, and from one-half to three-fourths, or seven-eighths of an inch in diameter. The thread is now released from the wire loop, and the wire withdrawn, leaving the thread in the centre of the roll. The roll is then formed into a ring by tying the ends of the thread together firmly. Making the roll two and one-half inches or less, and correspondingly thicker, a conical tampon may be made. Oakum or jute answers very well for the interior of the roll, but I prefer cotton for the outside."

TREATMENT OF POTT'S DISEASE BY A PERIOSTEO-PLASTIC OPERATION.

Dr. H. C. Wyman, of Detroit, in a lecture reported by Dr. Zina Pitcher, of the U. S. Marine Hospital Service, advocates a periosteo-plastic operation for the treatment of and prevention of deformity in Pott's disease of the spine. In cases of this disease that have gone on to a favorable termination, he argues, there is a firm bony splint, formed by a union or welding together of the articular and spinous processes of the diseased vertebra. Sufficent proof of the existence of this bony union as a natural means of repair is shown at post-mortem examinations. In a number of experiments on dogs conducted during the past five years, Dr. Wyman has demonstrated the possibility of obtaining such bony union by means of a periosteo-plastic operation, which may be briefly described as follows: An incision is made on either side of the spinous processes of the diseased vertebræ, and of the two adjacent healthy ones, so as to permit of the dissection of the periosteum from the spinous processes. The loosened membrane is then moved over to the adjacent spinous process, previously denuded, where it is fastened by sutures. By this means it is expected to obtain a firm osseous splint, the unbroken line of periosteum, formed in the manner above indicated, favoring an osseous deposit between the spinous processes. A firm bony splint is thus formed, which supports the diseased portion of the spine and permits no friction or pressure upon the carious bodies, in this manner relieving the tendency to greater inflammation and giving physiological rest. Dr. Wyman says that this operation will be most useful when it is resorted to early in the course of the disease, before angular curvature is present. The author of the method claims that it is the most rational one for the treatment of vertebral caries, and bases his assertion on the following grounds: 1. It is a faithful imitation of nature's plan of cure. 2. It accomplishes all that could be hoped for from the most thorough counter-irritation. 3. It imposes two or three weeks of rest in the horizontal position. Dr. Pitcher adds, that he has seen a number of cases of Pott's disease among the Indians of Southeastern Alaska. These usually result in a cure by bony anchylosis, the spine being straight and perfectly rigid. Such result is obtained by the treatment adopted by the parents of the children, which is to make the little patients keep the spine always in a horizontal position by walking about on their hands and knees.

WIPING OUT THE LARYNX IN CROUP.

Dr. Marcell Hartwig, of Buffalo, N. Y., writes: "Dr. Horace Green employed this method successfully as long ago as 1859. I have had a case in which there was cyanosis, and used a bit of sponge, fastened to a suitably bent probang. Green used a ten per cent. solution of nitrate of silver, but I used a simple sponge without any medicine. Such a procedure is easy, and is not fraught with the dangers of lost tubes, and of entrance of food into the lungs. The only danger is that of crowding membrane into the trachea. To obviate this trouble as far as possible, I propose to introduce a bit of sponge, fastened to a guide, within a silver catheter with open end. After the catheter is in the rima glottidis, the sponge is pushed out and then withdrawn, together with the instrument. The sponge, previously compressed in the catheter, would expand and bring away them embrane during its withdrawal. Of course, such manipulation would have to be done with rapidity. But if the catheter were of the requisite size for the age of the patient, the entrance of air would not be entirely prevented until the sponge was pushed forward. What results my be obtained by simply wiping the larynx remains to be seen, but this method previously employed will not prevent subsequent intubation, if the latter should be found to be necessary. Certain remedial agents may also be applied in this manner. After the first membrane has been removed, that which is formed again is much less firmly adherent."

THE ETIOLOGY OF ALOPECIA PRÆMATURA IDIOPATHICA.

Dr. Chevalier Q. Jackson, of Pittsburg, Pa., sends us a communication on this subject, in which he claims that the hat is responsible for very many cases of so-called idiopathic premature alopecia. Women are comparatively rarely troubled with this affection, and for the reason that their scalps are not so continually confined in hot unventilated hats. Another fact which points to the hat as the offending cause is that this form of baldness is not only limited to the head, but to that portion of it which is covered by the hat. There are many ways in

which the hat interferes with the vitality of the scalp and hair. There can be no doubt that a tight constricting hat-band greatly interferes with the circulation of the blood in the scalp, and consequently impairs the nutrition and vitality of the hair-follicles, by compressing the temporal artery and the terminal branches of the occipital. Then much damage also is done by excluding the light, not only direct solar rays, but also the indirect or reflected light. Then, again, that portion of the head covered by the hat is deprived of the beneficial effects of the reactionary congestion following exposure to cold air. While it is rare at the present time to see a bald woman, it was quite common in England and France at the time when it was fashionable for women to wear wigs and to build up mountains of false hair, cotton wadding, and pads. The writer has taken accurate notes of thirty-one cases of this affection, with special reference to the possible relation existing between it and the wearing of the hat, and concludes, from a study of these cases, that confining the head in a close and unventilated hat will cause the disease in cases in which a predisposition exists, and in certain cases it will produce it in the absence of any predisposition. Among the predisposing causes may be mentioned heredity, poor general health, mental exertion, worry, loss of sleep, etc. It has been argued that some of the above factors, alone or combined, may be sufficient to cause the disease, but if such were the case the alopecia ought not to be confined solely to that portion of the scalp which is covered by the head-gear.

CHIAN TURPENTINE IN THE TREATMENT OF CANCER.

Dr. John Clay, of Birmingham, England, writes as follows concerning the administration of Chian turpentine in cancer: "Success in the treatment of cancer by this drug depends upon, 1, the mode of its administration; 2, the stage of the disease; 3, the complications by which the growth is attended; 4, the persistence of the treatment. The idiosyncrasy of the patient will also influence more or less the rapidity of action of the drug; in one case the good results will be apparent in two or three weeks, while in another it will be as many months before the external appearances will give evidence of any beneficial action. If there is no perceptible increase in the growth in the course of two or three months, it may be relied upon that the drug is exerting a favorable action, and, other things being equal, the ultimate success of the treatment will depend upon perseverance in its continuance. Everything depends upon the purity of the drug, for there is an immense amount of adulterated and fabricated stuff in the market. There is *prima facie* evidence of the genuineness of the gum if no violet odor is communicated to the urine, and if no skin-rash or cutaneous irritation is manifested after the lapse of a few weeks. The external application of a chromic-acid solution (twenty or thirty grains to the ounce of water) to a cancer in a state of ulceration is sometimes useful. The following is the formula for preparing the mixture as published by the dispenser to the Queen's Hospital, Birmingham: 'An ethereal tincture is first made by mixing equal parts of Chian turpentine and ether, and shaking frequently in a well-corked bottle until all soluble matter is dissolved. An emulsion is then prepared in the following manner: Place in a large mortar two hundred and forty grains of powdered acacia and fifty grains of powdered tragacanth and one ounce of the tincture of Chian turpentine, mix, and add, all at once, a fluidounce of water, triturate until an emulsion is formed, and then dilute gradually up to eight fluidounces. Two fluiddrachms will contain seven and one-half grains of the pure drug—the initial dose. All trace of ether must be removed by exposure in an open vessel, preferably in the cold.' Those cases are the most suitable for treatment in which the disease affects the skin or mucous surfaces, and the earlier the treatment is begun the better is the chance of success. When the lymphatics are extensively involved, or when the disease has invaded the peritoneum, pleura, or vagina, the drug can be recommended merely as a palliative. In cancer of the uterus or rectum, if treatment has not been begun very early, disease of the kidney (not necessarily of a malignant character) is apt to arise. If this condition becomes manifest, the action of the drug will require careful watching, and it may be necessary to abandon its administration altogether. It is advisable, after the medicine has been taken for two months, to omit it for two days in each month, beginning again with it in the same dose that was being given at the time of its discontinuance. Opium, in large doses, is antagonistic to Chian turpentine, and should be given only when absolutely necessary because of severe pain, and then only in small doses—about seven minims of the tincture, incorporated in the mixture. The combination of resorcin with the Chian turpentine (two drachms to eight ounces of the above mixture) is sometimes beneficial. The mixture is given in doses of one teaspoonful in cold milk three times a day, after meals, increased in two weeks to two, and in two weeks more to three, teaspoonfuls. Its administration is to be persevered in for a long time. Too speedy results are often expected from the remedy, and hence it may be abandoned too early before it has received a fair trial. If the disease seems to be arrested at the expiration of a few weeks it is quite sufficient to justify a continuance of the drug. After the arrest of the disease the remedy must be continued until some obvious change takes place, and it must be administered continuously, in increasing doses, under any circumstances, even if some apparently discouraging conditions arise." Dr. Clay adds some remarks concerning the administration of the remedy in individual cases, which, however, we are obliged to omit on account of the pressure on our columns.

RUPTURE OF THE BLADDER IN AN OX FROM IMPACTED CALCULI.

Dr. G. W. Squires, of East Avon, N. Y., writes: "A farmer lost a valuable ox, with the following history and autopsy: He had been in the habit of watering the team at the house well, which water was strong in the ingredients of lime. The ox was twelve years old, and had drunk of this water eleven years. It had at times shown signs of vesical trouble, but never to a degree to incapacitate him for work. He was found in the stable one day in great distress, lying down and getting up, turning round and round, swinging his head around to his haunches, and visibly in excruciating agony. He remained in this condition two days, all remedies failing to alleviate, but at the end of this time he was found lying down, apparently comfortable; he ate and drank a little, but with fastidious relish. For three days he lay down most of the time, and was noticed to be very thirsty—would drink great quantities of water. He now began to bloat, and there was a discharge of frothy water from the mouth and nose, increasing in quantity until it flowed almost in a stream. The ox appeared to be in little pain; died on the seventh day. The examination revealed rupture of the bladder at the fundus, with slight hemorrhage. The abdomen contained eight common-sized pailfuls of water, of a urinous color and odor. Numerous small calculi, from the size of a number six shot to a good-sized pea were found impacted at the neck of the bladder. The bladder contained one hundred and fifty of these calculi, about one hundred and twenty-five of them being of the smaller size. They were most of them perfectly round, and of surpassing smoothness and beauty. The calculi, becoming impacted in the neck of the bladder, doubtless caused spasmodic closure of the urethral outlet, causing retention of urine, until the viscus was dilated to such a degree as to rupture, after which the pain was alleviated, the water passing through the tear into the abdominal cavity."

Progress of Medical Science.

Sulphate of Sparteine.—From his own researches into the action of sulphate of sparteine, Dr. Gluzinski draws the following conclusions: 1. The main effect of sparteine consists in slowing the cardiac action and raising the blood-pressure, which effect in cold-blooded animals is more pronounced than in the warm blooded (mammals). 2. In the latter there may be distinguished three periods of the drug's action, in the first and third of which the retardation is more marked than in the second (in this even a quickening of the heart may sometimes be observed). The phenomena are to be explained by changes in irritability of the pneumogastric nerves and of the cardiac muscle. 3. Reflexes are at first increased, but subsequently lowered. 4. Death follows from asphyxia, and is dependent, not only upon a lesion of the medulla oblongata, but also upon that of the respiratory muscles. 5. Therapeutically, sparteine may be of use in such cases of uncompensated cardiac disease (*a*), "where the patient's state does not permit us to wait for a full development of the action of digitalis," (here sparteine may be given as adjuvant to digitalis); (*b*) where digitalis remains inactive; and (*c*) where the latter is contra-indicated. 6. In uncompensated cases the administration of sparteine is followed already in an hour by an improvement of the pulse and subjective symptoms; cardiac arhythmia, however, does not disappear. 7. As to energy of action, sparteine is inferior to digitalis.—*The London Medical Record.*

The Causes of Hæmoptysis.—In a work by M. Dejean, the author states that hæmoptysis is not always a symptom of incipient pulmonary phthisis, as is generally supposed, but may be due to dilatation of the bronchi from a varicose condition of the capillaries, or miliary aneurisms of the bronchial mucous membrane. Laënnec, who first described this affection, observed cases of hæmoptysis in which the necropsy revealed several bronchial dilatations, without any sign of the presence of tubercles. Barth, Gombault, Balzer, and other authors have often seen hæmoptysis in patients affected with bronchial dilatations, and attributed the bleeding to capillary aneurisms in the walls of the dilated bronchi. An important feature of this form of hæmoptysis is that the blood which is brought up is rarely frothy, as it is in the case of tubercular disease. The differential diagnosis between bronchial and other kinds of hæmoptysis may be established in difficult cases by the presence or absence of bacilli, as has been proved by Dr. Cochez.—*The British Medical Journal.*

O'Reilly's Method of Arresting Post-partum Hemorrhage consists in passing the vaginal nozzle of a good syringe through a sponge about four inches in diameter; then, moistening the sponge, it is compressed with the fingers and carried up into the fundus uteri. An assistant attends to the water-supply, an abundant injection of which quickly brings on uterine contractions, and the hemorrhage ceases, with no retained clots. The water injected flows back through the sponge, and if impregnated with some sort of antiseptic, such, for example, as one grain of mercuric chloride to the pint, would tend greatly to lessen the danger of carrying septic matters either in the sponge, the syringe, or the water used.—*Progress.*

The Danger of Ice in Post-partum Hemorrhage.—Several cases in which post-partum hemorrhage was successfully stopped by the introduction of pieces of ice into the uterus have been followed by symptoms of septicæmia. This fact, taken in conjunction with the recent researches of Prudden as to the presence of living bacteria in ice, may perhaps point to direct septic infection from the use of ice. Under any circumstances, hot water is probably preferable as a hæmostatic agent, and the possibility of conveying septic germs in ice thus brought forward is another and still stronger argument against the employment of the latter.—*Medical Press.*

Metastasis in Erysipelas.—An interesting contribution has been lately made to the pathology of erysipelas by Dr. von Noorden. It is based upon a fatal case of facial erysipelas, in which there was also suppuration in the sheaths of the extensor tendons of the right hand, parenchymatous nephritis, acute oöphoritis of the left side, and acute swelling of the spleen. It was concluded that this was an instance of secondary or metastatic infection of erysipelas. The blood in the cardiac cavities and the pus from the inflamed hand were found to contain large quantities of a streptococcus which neither microscopically nor by cultivations could be distinguished from streptococcus erysipelatis or from streptococcus pyogenes. Inoculations of the cultures obtained from the blood were made in the ear of rabbits. In three instances only redness, without swelling or suppuration, occurred; in one of these cases only isolated chains of cocci were found in the lymphatics of the ear. In a fourth rabbit there was no local effect, but death followed in two days, and the blood was found to contain numerous streptococci; while in the fifth rabbit redness of the ear appeared on the sixth day, and numerous chains of cocci were detected in the lymphatics of the amputated ear, yet on the twelfth day, when the animal died, no cocci were found in the blood. These variable results led Noorden to conclude that animal experimentation was an insufficient test of the species of streptococcus; and further that, contrary to general opinion, the erysipelas-coccus may, under certain conditions, gain entrance into the blood. This infection may, he thinks, explain the occasional occurrence of secondary pneumonia; but Weichselbaum states that in such cases the pneumonia is not due to the erysipelas-coccus, but to the diplococcus pneumoniæ, and that it is incorrect to speak of an erysipelatous pneumonia. The case related by Noorden was probably one of pyæmia, due to infection by the streptococcus pyogenes.—*The Lancet.*

Transperitoneal Nephrectomy.—At a recent meeting of the Paris Surgical Society, M. Terrier communicated a note on a new method of performing transperitoneal nephrectomy. The abdomen is opened in the middle line, and the intestine pushed aside so as to uncover the peritoneal membrane covering the kidney. A vertical incision is then made in the membrane, the edges of which are held back with clamps. After removal of the tumor, the pedicle and the ureter are tied and brought forward through the peritoneal incision to the abdominal wound, where they are secured. In this manner the peritoneal cavity is closed on all sides. M. Terrier claims that this operation does not necessitate drainage through the loin, as has generally been supposed.

The Nomenclature of Skin-diseases.—From a consideration of this subject, with especial reference to hybrid, syphilitic, and medicinal eruptions, Dr. Liveing (*The British Medical Journal*, May 7, 1887) concludes that:

1. When two skin-diseases coexist, they are generally quite distinct, and should be called by their well-recognized names.

2. That diseases are not natural, and do not follow the laws of natural development.

3. That it is very doubtful whether hybrid or crossed diseases exist at all, and that certainly there is no sufficient justification for a hybrid nomenclature.

4. That syphilitic skin-diseases differ from ordinary skin-diseases in their etiology, pathology, and treatment; and that this difference should be fully recognized in our nomenclature.

5. That medicinal rashes are not diseases of the skin, but simply eruptions, and should be so named.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 16, 1887.

THE USES OF ANTIPYRETIC DRUGS IN NERVOUS DISORDERS.

THE new antipyretic drugs, antipyrin and antifebrin, or acetanilide, have actually accomplished very little along the lines on which they first won their reputation. As symptomatic remedies, for occasional use in high fever, no doubt they serve a purpose. But for the systematic treatment of continued pyrexia of any type they are of no value, or may even be considered dangerous.

In other directions, however, both these drugs have shown powers which entitle them to a place in therapeutics. In the treatment of acute rheumatism both antipyrin and antifebrin act well, not better than the salicylates perhaps, but in many cases accomplishing the same result with less gastric or cerebral disturbance, and in some cases relieving the symptoms when the salicylates fail. Antipyrin has also been found to be an excellent remedy in febrile headache and in migraine. In addition to evidence of this already reported in THE MEDICAL RECORD, Dr. T. S. Robertson, at a recent meeting of the New York Neurological Society, reported a large number of cases illustrating the analgesic effects of this drug.

Antifebrin, or, better, acetanilide, holds a still higher place as a nervine, if we may judge from the experiences of Dujardin-Beaumetz and his pupil Weil.

Professor Lepine first discovered its sedative properties upon the nervous system. Its physiological action was further investigated by Dr. Weill (*Bull. de Ther.*, 1887, p. 150), who showed that it was a special sedative, and also that, given to non-febrile patients, it had no toxic effects in ordinary doses. The dose used when it is given as a nervine is from six to ten grains three or four times a day. This amount may be kept up for weeks without producing any of the physiological effects seen when the same dose is given to fever patients. It is best given dissolved in wine, or some alcoholic elixir, since it is not soluble in water.

Dujardin-Beaumetz has found acetanilide of value in combating pain in general, the special pains of locomotor ataxia, and in the treatment of epilepsy. In pure facial neuralgia the drug is inferior to aconite, but in those headaches which are of a rheumatic character, and in muscular or arthritic pains, the drug fully equals salicylic acid, and causes no disagreeable cerebral effects. In cases of locomotor ataxia the fulgurating pains were stopped temporarily or permanently by acetanilide. Dr. Signé, of Montpellier, reports similar results to those of Dujardin-Beaumetz in this class of cases.

As to the use of the drug in question in epilepsy, a good deal of caution is expressed. Beaumetz reports three cases in which the epileptic attacks ceased after acetanilide was given. But Dr. Signé, who used it in two cases, got no good results at all. Hence many more trials must be made before anything definite can be said.

A PILE-RIDDEN PEOPLE.

AMERICANS have been accused of being excessively nervous, very hard-headed, somewhat over-religious, and miserably dyspeptic. It was not until the present summer, however, that we are met with the charge of being, as a nation, the victims of piles. At the recent meeting of the German Surgical Congress, Dr. Lange said that in America hemorrhoidal disease was very common, not only among men, but also among women. This was in consequence of the very abundant diet, for the ladies took hardly any exercise at all, and the men were too preoccupied about business matters to pay attention to the state of their bowels. "Among hundreds of persons taken at random, scarcely a dozen would deny having piles if the question were asked, and it would in all cases be safe to ask the patient at once the name of his favorite purgative."

So, it appears that the American diathesis is hemorrhoidal. It has heretofore been considered that neurasthenia was our pet disease. But, if twelve per cent. of this great nation suffer from hemorrhoids, the pre-eminence of neurasthenia must lapse at once into innocuous desuetude.

It is less flattering to national vanity to know that wherever eight Americans are gathered together there is one case at least of piles, and that hemorrhoidal protrusions are coextensive with that magnificent territory over which the star-spangled banner waves. It is well, however, to learn of our infirmities, and try to correct them with maturing years and suitable topical applications.

Dr. Lange's remarks, therefore, upon the surgical treatment of hemorrhoids may be quoted here. He said that there was no need to invent a safe and easy method of operation for piles; it was only necessary to improve the present methods in two respects, namely, to lessen the severity of the operative procedures, and to shorten the duration of the treatment. The injection of concentrated carbolic acid into the hemorrhoidal masses had long been practised by quacks in the Western States of America, and at length legitimate practitioners were induced to make trial of the method. Dr. Lange spoke well of the results obtained thereby. The operation was as simple as possible, and no anæsthetic was required. The rectum should first be thoroughly emptied; then the piles must be brought down; and, after applying iodoform ointment to the mass, a solution of carbolic acid, more or less concentrated according to circumstances, should be slowly injected. Some surgeons used equal parts of glycerine and carbolic acid. In the case of large hemorrhoids, it was advisable to turn the point of the needle in various directions. Most practitioners allowed the patients to return at once to their business; but Dr. Lange usually insisted on their

remaining quiet for some days. After injection, the tumors began to swell somewhat rapidly, and assumed a glass-like appearance. In the case of internal piles, the operation was painless; but, in external hemorrhoids, sharp pain generally came on suddenly half an hour afterward. This should be relieved by suppositories. The next day the patients were quite well. The operation was repeated at intervals of three or four weeks. Dr. Lange had never observed any ill-effects, except slight sloughing. In the case of bleeding piles it was advisable to seek for the spots from which the hemorrhage came and to inject at those places, as the patients then recovered very quickly. Dr. Lange had performed the operation on forty or fifty patients only once, and in only one case had he been obliged to repeat it after two days.

THE NOMENCLATURE OF DRUG ERUPTIONS.

An English dermatologist utters a protest in the *British Medical Journal* against the current habit of attaching definite names of well-recognized skin-diseases to the various eruptions produced by drugs. He instances the fact that iodide of potassium causes, in some patients, pimples, and in others, blebs. The eruption has been called by Bumstead "pemphigus," and by Hutchinson "hydroa." Now these observers did not mean that the patient was actually suffering from either of these diseases, but that their eruption resembled, in its general type, "pemphigus" or "hydroa." The corollary is drawn that the proper designation should be "blebs from iodides." "Medicinal rashes," says the writer, "are not diseases of the skin, but simple eruptions."

This may seem a somewhat trivial matter, but it is one in which the point is well taken. It is simply an instance of the loose use of technical language where, nevertheless, we all understand each other. This license causes no trouble to the practitioner, but it is very apt to confuse a student, whose ideas about skin-diseases are apt to be very misty, and who contents himself, for a while, at least, with the brief classification of "eczema" and "not eczema."

THE ALLEGED CURABILITY OF GENERAL PARALYSIS OF THE INSANE.

It is generally acknowledged at the present day that general paralysis of the insane is an incurable affection, the tendency of which is, with occasional intervals of apparent improvement, constantly toward a fatal termination. Yet cases of this disease are from time to time reported in which a lethal issue has apparently been averted by treatment, and it has been suggested that possibly these cases were not true general paralysis, but that there is another affection bearing a close resemblance to it, which, however, is not always fatal.

In an article in the *Annales Médico-Psychologiques* for January, 1887, M. Baillarger seeks to differentiate these two allied disorders. There are, he says, two distinct affections, one, general paralysis of the insane, caused by chronic periencephalitis; the other, pseudo-general paralysis, produced by simple circulatory troubles. The differential points are, he asserts, simple and easily recognized. True general paralysis presents the pathognomonic signs of dementia and paralysis, while pseudo-paralysis commences by maniacal or melancholic delirium without being preceded by dementia or paralysis, and accompanied or not, as the case may be, by symptoms of muscular ataxia.

The following are the conclusions which the author has drawn from his investigations in this field:

1. There have hitherto been confounded, under the designation of general paralysis of the insane, two distinct affections.

2. In addition to general paralysis there is a special form of insanity characterized by irregular and incoherent ideas of grandeur, hesitancy in speech, inequality of the pupils, etc.; that is to say, by all the classical symptoms hitherto attached to the early period of general paralysis of the insane.

3. This form of insanity, distinct from general paralysis, cannot, however, be classed with simple insanity, and consequently it should be assigned to a special place in the nomenclature of diseases.

THE PAUPERIZATION OF THE WEST SIDE.

In 1875 there were four or five dispensaries in the poorer districts on the west side of the city. Out of the whole population, then, only about 25,000 were treated annually at these institutions. A patient, if sick, went to a doctor and paid him, if he could. If not, there were plenty who would treat him for nothing when the circumstances were explained.

In 1885, on the other hand, nearly 60,000 persons were treated *gratis* at the dispensaries. Instead of one large institution there are now three, all doing active work, and a fourth will be established this fall, when the College of Physicians and Surgeons opens in its new building.

Physicians practising on the west side observe that the people are getting educated up to dispensaries, and now get their medical service free as often as possible. In the past ten years an immense number of people have moved to the west side. The majority are not of the poorer tenement-house class, but ought to be able to pay the doctor.

IMMIGRANTS AND INFANTILE MORTALITY IN AMERICA.

Dr. Eklund, of Stockholm, has compiled statistics showing the number of deaths annually per hundred of all deaths among infants under one year of age. The lowest death-rates (14.3 to 26.2) are found in Belgium, Denmark, Sweden, England, and Switzerland. The highest (31 to 48 per 100) in Austria, Germany, and Russia. The cities with the lowest rate are Paris (30.8), and St. Petersburg (32.5), while the highest death-rate is in Berlin (58.1)! a city remarkable for its zeal in the pursuit of medical science and art.

Dr. Eklund states that the mortality of infants under one year of age in Europe generally is twenty-five per cent. of all deaths.

He tells us also that in the large cities of the United States the infants dying under one year of age average fifty per cent. of the number born.

The high death-rate credited to America is ascribed by Dr. Eklund to the fact that the European defective classes, whose natality and infantile death-rate are enormous, are forcibly exported in great numbers to this country, a large proportion going to our cities.

It is very true that the numbers of our sick and defective classes are enormously swollen by the immense tide of immigration. The figures of Dr. Eklund are incorrect for this city, however, where only twenty-five per cent. of the whole number born annually die within a year. Nearly three-fourths of the infants in this city have foreign-born mothers, and it is safe to say that four-fifths of the infant mortality is among the children of the immigrants.

News of the Week.

Our St. Louis exchanges complain that their delegates to the American Medical Association were not treated with proper hospitality, the delegates themselves referring "in bitter terms to the very unsocial features of the entertainments given."

More Money is needed for the International Congress. Present accounts give the amount raised, aside from the Congressional appropriation, as not above $5,000. We trust that the gentlemen who have talked so bravely about the prospects of the meeting will not stop with words.

Another Medical School for Women.—The St. Louis *Medical and Surgical Journal* states that St. Louis is to have a medical school for female students exclusively, "the means having been subscribed by wealthy citizens." We trust that the latter item is correct. We want no more Lazarus medical schools.

The Peoria "Journal" views with some doubt the possible working of the new Illinois Medical Practice Act, by which the practice of medicine, even by the simple process of laying on of hands and "shooing" the disease away, is a thing of difficulty. Still, it adds, a man can go to the drug-stores and get three fingers of whiskey and two grains of quinine and be all right. That sweet boon is not denied him, and as long as he can do this and keep off "the shakes" he can grin defiance at the State board.

Indian Doctors.—There are now twelve shows of these travelling in the West, each one having a band, a man who pulls teeth gratis, and one who sells patent pain-exterminating oil.

The Clinton County Medical Society of this State celebrated its semi-annual meeting, at Plattsburg, with an excursion on the lake and a dinner.

Another New Hypnotic, recommended by Professor von Mering and Professor Jolly, is amyl-hydrat, a tertiary amyl-alcohol. Von Mering has used it for insomnia in sixty cases, the dose being three to five grammes.

Board of Examiners in Michigan.—A bill creating a board of examiners in medical practice has passed the Michigan Legislature.

Headache and Poisoned Hats.—Dr. Joseph F. Gerster, in the *American Grocer*, describes a case of poisoning from wearing a hat with sweat-bands colored with lead. The chief symptom was headache. It is not uncommon to use lead in preparing the leather for sweat-bands, but there is rarely any dangerous amount.

The Death of Professor Akin C. Muller, of the Medical Department of Wooster University, occurred recently. At a meeting of students, resolutions warmly eulogistic and sympathetic were adopted.

Dr. John C. Gordy, a well-known physician in Western Louisiana for many years, died on July 11th, at Franklin, La., aged seventy-eight. Dr. Gordy was for thirty years Grand Lecturer of the Grand Lodge of Masons.

Dr. George Engs, of Newport, R. I., died on July 7th, of heart disease, aged forty-five. He was a graduate of the Harvard Medical School, and had studied abroad.

Adulteration of Drugs.—The New York *World* employed a chemist to examine samples of drugs in our local pharmacies. He reports: "The examination of the drugs submitted to me shows little adulteration. With the exception of one sample, pink-root, there was no case of substitution discovered, and it is possible that this sample was sold by mistake. Samples of oil of winter-green and solution of citrate of magnesia, in which the substitution of a cheaper article was rather expected, were found to be genuine. Oil of sassafras is sometimes used to adulterate oil of winter-green, and occasionally a solution of tartrate of potassium is labelled and sold for citrate of magnesia. In a few cases drugs were found to be of an inferior quality, notably ipecac, in which the medicinal portion of the drug had entirely disappeared; senna, which contained decayed leaves possessing no value; gentian, long kept and worm-eaten; taraxacum, aconite, and rhubarb, inferior specimens were gathered. The most important adulterations discovered were in the tinctures of nux vomica and opium—articles over which the retail druggist has absolute control."

Jubilee Medical Honors.—Our English medical brethren apparently expected some high honors to be bestowed upon them on the occasion of the Queen's Jubilee. We learn, however, that Her Majesty was "graciously pleased" to make knights of Dr. Garrod, Mr. G. H. Macleod, and Dr. Aitken. One veterinarian, Mr. H. L. Simpson, was also made a knight. Various minor decorations were also bestowed. But, plainly, the English doctor is not yet thought good enough to be made a peer.

Gaseous Enemata in Phthisis.—The use of these enemata has been entirely abandoned in the fourth division, Bellevue Hospital, where they have been earliest and longest tried.

Dr. C. B. Nancrede has accepted an invitation to deliver the Course of Lectures on Surgery at Dartmouth College, New Hampshire, in the absence of Dr. P. S. Connor in Europe.

The Inventor of the Operation of Cataract-extraction.—M. Panas has offered to the Academy of Medicine of Paris a bronze medallion of Jacques David, the inventor of the operation of cataract by extraction. A subscription is being raised to erect a monument to the memory of the distinguished oculist, at his birthplace, La Barre, in Normandy.

The Late Dr. Friedländer's excellent journal, *Fortschritte der Medicin*, will be continued under the editorial charge of Professor Unverricht, of Jena, and Professor Weigert, of Frankfort.

Medical Berlin and Medical New York.—Berlin has 10 medical societies; 30 hospitals, with 5,000 beds; 1 medical school; 1,150 physicians, who get from fifty cents to $1 per visit. New York has over thirty medical societies; 46 hospitals, with 6,000 beds; and about three thousand physicians, who receive $1, $2, and $3 per visit.

The Illinois State Medical Society.—The Peoria *Medical Monthly*, from between its new and attractive covers, utters a cry of warning regarding the Illinois State Medical Society. The meetings, it says, are not well attended, and the organization has not its due influence as the organ of four thousand regular physicians. At the last meeting the attendance was only about one hundred, the year before 105, and the year before that 145.

A Death from Antifebrin recently occurred in the practice of Dr. E. Von Quast, of Kansas City. A child with high fever was ordered a mixture containing antifebrin, with the instruction that one dose (containing four grains) be given in the morning, to be repeated in the evening if so ordered at the second visit of the doctor. The father of the child, believing that "if a little is good, a considerable must be better, in spite of the protests of the mother, gave the medicine every two hours during the day. In the evening, upon the doctor's calling, he found the child cyanosed and in extreme collapse, and, notwithstanding all efforts, the child died from the overdose of antifebrin.—*Kansas City Medical Index.*

An Interesting Malpractice Suit.—A man named Louis Brown, while working at a saw-mill, received a splinter one-fourth of an inch in width and seven-eighths of an inch long, which entered his orbit just below the globe of the eye and became imbedded in the retina. Dr. Casebeer and his partner, Dr. Metheney, of Fort Wayne, Ind., were called, and discovered nothing but a superficial flesh wound. Pus formed in the face and the sliver was pulled out, three weeks afterward, by a man named Jinks, who used his jack-knife. Brown lost the sight of his eye, and brought suit in the DeKalb Circuit Court against Drs. Casebeer and Metheney, laying his damages at $5,000, for malpractice. Among the witnesses who gave expert testimony were Dr. Frothingham, Professor of Ophthalmology at the University of Michigan, and Drs. Dills, Porter, and Wheelock, of Fort Wayne. Their testimony relieved the attending physicians of any blame in not discovering the imbedded splinter, and it was given with so much distinctness and unanimity as to lead many of the jurymen to believe that their expressed opinions were biased by a friendly feeling toward their professional brethren whose reputation was at stake. Dr. Frothingham produced the stem of a tobacco-pipe which had been driven into a man's face and was not discovered by Dr. Smith, of Detroit, nor was its presence even suspected until it worked its way to the surface. The jury, after being out for twenty-three hours, disagreed. They stood eleven for the plaintiff and one for the defendant.

Surgical Operations upon the Spinal Cord.—We believe that there have been at least two attempts to relieve pathological conditions of the spinal cord by surgical interference. In both instances the operations failed. We learn now, however, that a possibly successful attempt has been made in London. The *British Medical Journal* states that on June 9th, Mr. Victor Horsley removed a tumor in the dorsal region of the spinal cord from a patient under the care of Dr. Percy Kidd. The patient had been seen by Dr. Gowers, who diagnosed a localized neoplasm, and suggested operative interference. The tumor measured about one inch and a fourth by half an inch; it was situated within the dura mater, and apparently grew from the ligamentum denticulatum of the spinal cord. It compressed the latter severely, causing violent spasms, pain, and complete paraplegia. Although the operation was necessarily prolonged, the temperature has never reached 100°, and the wound is now practically healed. The patient has already recovered some power over the bladder, and the spasms and pain are rapidly diminishing.

How Men and Women should Dress.—*The Epoch* devotes three of its recent issues to a publication of the opinions of various people, including two medical women of the irregular type, on the subject of dress. This subject is a rather threadbare one, and we confess to having found nothing very novel in the wealth of views furnished us by *The Epoch*. It will not be of much use to talk about how men and women should dress until it is the fashion not to dress in fashion. Meanwhile the primitive savage and the introspective valitudinarian will form the two great classes on which dress-reformers can best exercise their taste.

Obituary.

JARED LINSLY, M.D.,

NEW YORK.

Dr. Jared Linsly died, on July 12th, at Northford, Conn., where he was born in 1803. He was graduated at Yale in 1826, and subsequently at the College of Physicians and Surgeons of this city in 1829. Since that time until his last illness he was actively and successfully engaged in the practice of his profession. He was well known by the old residents of New York, and was distinguished in his profession for his learning and practical skill. His life, too, has been signalized for his benefactions to the poor. He was a Trustee of the College of Physicians and Surgeons, and of the Ophthalmic and Aural Institute; and Consulting Physician to the Asylum for Lying-in Women, and to the New York Dispensary and the Presbyterian Hospital. He was a member of the New York Society for the Relief of the Widows and Orphans of Medical Men, and one of its managers and benefactors. He was also a member of the New York Physicians' Medical Aid Society, and of the Medical Society of the County of New York.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 9, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. W. H. Porter read the

REPORT OF THE COMMITTEE ON MICROSCOPY,

signed by Drs. J. S. Thacher and G. C. Freeborn. In the specimens of ulcers of the pharynx and larynx presented by Dr. R. Van Santvoord, February 9, 1887, the committee were unable to find any evidence of tubercle.

Dr. Porter also presented a collection of

SMALL CALCAREOUS CONCRETIONS FROM THE SPLEEN.

Dr. H. J. Boldt presented a specimen of what he called

SYPHILITIC SALPINGITIS,

because there was no history of gonorrhœa; but there was a history of chancre, and the woman was suffering from well-developed secondary symptoms at the time of the operation, which was performed on account of the severe pain from which the patient suffered. The wound and the patient did well.

Dr. Boldt also presented a specimen of

PROLAPSED CYSTIC OVARY,

removed from a woman who had been under treatment about one and a half year without obtaining relief. The symptoms were intense backache, headache, dyspepsia, pain in the hypogastrium and inguinal region, severe dysmenorrhœa lasting throughout the entire period, and distressing cardiac palpitation. It had been two or three months since the operation was performed, and all the symptoms had disappeared except the palpitation, which had been very much modified.

Dr. Frank Ferguson presented a specimen of

CARCINOMA OF THE BLADDER,

removed from the body of a man, sixty-one years of age, a native of Ireland, a widower, and a painter by occupation. He was admitted into the New York Hospital on January 29, 1887. Two years previously he first complained of stinging pain in his testicles and severe pain in the region of the bladder during micturition. These symptoms had continued, and he applied at the hospital for treatment. He had never had gonorrhœa.

On admission he was weak and anæmic. Within the last two years he had lost considerable flesh. Micturition was frequent and painful. No. 22 steel sound was tightly grasped in the prostatic urethra. Examination of patient by the rectum revealed the prostate enlarged and indurated. The urine was alkaline and had a specific gravity of 1.014. It contained a trace of albumin. Microscopical examination revealed quantities of mucus and pus. He always suffered constant, dull pain, but his pain was quite severe during micturition.

During his residence in the hospital he passed daily from thirty-seven to sixty ounces of urine, micturating from ten to fifteen times. During the last ten days of his life he vomited daily a greenish-yellow fluid. He gradually and constantly failed, and died on the afternoon of the 15th of the following February.

The autopsy revealed the bladder moderately distended with urine, pus, mucus, and grumous material. There was a tumor at the base of the bladder, involving the entrance of both ureters. The tumor, on opening the bladder, appeared slightly raised above the mucous membrane, was circular in outline, and measured one and one-quarter inch in diameter. The connective tissue between the rectum and the bladder, and also the seminal vesicles, were invaded by the tumor. Microscopically, it was composed of fibrous tissue and epithelial cells; the fibrous tissue arranged into alveoli which were closely packed by epithelial cells of small size. The ureters were greatly dilated; the left more than the right. The outlet of the ureters could hardly be traced through the tumor. The pelvis of the left kidney was very greatly dilated; nearly the entire organ was destroyed. The pelvis of the right kidney was also dilated. The cortex of each organ showed the lesions of chronic diffuse nephritis. The stomach was congested, and its mucous membrane was thickened. The other organs were normal.

FOREIGN BODY ENTERING THE CRANIAL CAVITY THROUGH THE ORBIT.

Dr. J. A. Wyeth presented a piece of a fence-rail that Dr. Cross, of Decatur, Ala., four years ago, removed from the cranial and orbital cavities of a negro who had been thrown from a railroad train while in motion and pitched headlong into a pile of rails. As he went, head on, a piece of a rail was plunged into the right eye in such a manner as to push the eye out of the orbital cavity almost completely, it being necessary to clip off only a few connecting portions of lacerated tissue to separate it entirely. While dressing the wound the doctor felt something within the orbit, which he removed and found it to be a piece of wood two and three-fourths inches long, three-fourths of an inch in its greatest diameter, and in its smallest diameter one-half of an inch. After the piece of wood was removed some brain-matter oozed through the orbital cavity. The man recovered without cerebral symptoms, and subsequently suffered no inconvenience except that attending the loss of an eye. This case was an additional illustration of how severely the brain may be injured without producing serious symptoms.

Dr. A. Palmer Dudley presented a

TUMOR REMOVED FROM THE RIGHT PAROTID REGION

of a woman twenty-eight years of age, married six years, and the mother of two children. This was the third operation, the first being performed four years ago. The patient came to him from Dr. N. P. Dandridge, of Cincinnati, with the following letter, dated February 25, 1887:

"Mrs. A—— first came under my care in September, 1885, for a swelling in the right parotid region. Some eighteen months before, a small tumor had been removed by Dr. Porter, of Boston. Dr. Porter, in answer to a letter, stated that the growth was a small circumscribed fibroid tumor, distinctly incapsulated, and enucleated without difficulty. No microscopic examination was made, but no suspicion was entertained that the growth was anything but a simple fibroma. When first seen I found a distinct swelling beneath the cicatrix of the former operation, to which it seemed adherent. This swelling was distinctly movable on the underlying tissues, and when seen a second time, some two weeks later, seemed to have somewhat increased in size, and I advised its immediate removal. This was accomplished on September 30, 1885. The cicatrix and adjacent skin were included in the superficial incision, and the surrounding fat in the deeper part of the wound was freely removed. No circumscribed tumor was found, and no suspicious tissue was left behind. The mass removed was most carefully examined microscopically, and nothing but a somewhat dense cicatrix and fatty tissue found. The wound healed readily. For some months there has been a steady increase in the size of the growth, and it is now considerably larger than when removed, in September, 1885. For some months I have only seen Mrs. A—— at long intervals, and have noticed each time a steady increase in the prominence of the swelling."

The growth seemed to be encysted, but the sac was so attenuated and spread out that Dr. Dudley was unable

to say whether or not he removed all of it. The specimen was referred to the Committee on Microscopy.

Dr. Dudley also presented

A LARGE FIBROID, TOGETHER WITH THE UTERUS AND ITS APPENDAGES,

which he had removed the day before. The woman did not know that she had it until about ten days ago, when for swelling of the right leg she sought medical advice.

She was forty years of age, had never borne children, and she had never been troubled with her menstrual function. As soon as she learned of her condition she insisted that an operation be performed, which Dr. Dudley did, and found the ovaries and tubes and uterus so intimately connected with the growth that it was necessary to remove the whole. There were no adhesions. It was removed through an incision extending from the pubis to two inches above the umbilicus. The pedicle was transfixed and ligated in parts, cut short, touched with carbolic acid, and dropped back. The temperature of the patient was 100°, and her pulse 90. No morphine required to-day.

[At the stated meeting, March 23, 1887, Dr. Dudley reported that the patient was convalescent. On the sixth day he attempted to move the bowels, and did not succeed until several hours had been consumed in the use of ox-gall enemata, turpentine stupes, and a Seidlitz powder. Septic symptoms developed at once, and his patient nearly died; all of which, he believed, would have been avoided, had her bowels been moved earlier. He believed that he had lost two patients from septicæmia due to what he thought he had learned in the present case—namely, neglect to move the bowels sufficiently early. He also believed that the septic symptoms which frequently develop on the fifth or sixth day after laparotomy were frequently due to consequences attending failure to move the bowels.].

Dr. Ira J. Van Gieson presented

A MISPLACED KIDNEY,

removed from the body of a male thirty years of age.

The right kidney was found in the pelvic cavity; lying against the sacrum, behind the peritoneum, the superior apex is on a level with the pelvic brim, and its internal border follows the median line of the bodies of the sacral vertebræ. The renal artery is given off from the aorta at its bifurcation with the hilus, is situated on the anterior surface, and runs from the superior apex to about the middle of the anterior surface of the hilus. The ureter is situated inferiorly, the artery superiorly, and the vein lying between. The ureter measures seventeen centimetres.

Dr. Van Gieson also presented a specimen of

ATROPHIC KIDNEY WITH DILATED PELVIS.

There was nothing in the history referring to the kidneys.

Autopsy.—Heart: slightly enlarged; valves normal; atheroma of aorta. Lungs: emphysema; œdema; chronic bronchitis. Liver and spleen normal. Left kidney surrounded by dense, adherent tunica adiposa, containing calcific deposits; the kidney is small, measuring six by three centimetres; the pelvis is dilated, containing an amber-colored fluid; the cortex and capsule measure but two to three millimetres in thickness; ureter normal. Right kidney slightly enlarged, capsule adherent; the cortex is congested and rough.

Microscopical examination.—The cortex in places is one to two millimetres in thickness; the capsule is thickened. In the cortex there is an increased amount of connective tissue. This cortex is composed largely of altered glomeruli. The capsules of the glomeruli are thickened, and the tuft of vessels is changed to a mass of connective tissue in places calcified. Many of the tubules are present containing casts; there is obliterating endarteritis. The right kidney shows a moderate degree of chronic diffuse nephritis.

Dr. William P. Northrup presented a series of specimens removed from the body of a child that died of

GENERAL TUBERCULOSIS,

which were interesting on account of the extent and severity of the lesions.

Male mulatto child, aged two, returned to the New York Foundling Asylum from its hired nurse, in the city. It suffered from almost uninterrupted convulsions at this time; no diarrhœa nor vomiting. Two days later the child died. No further history could be gained, and no further symptoms were made out. On autopsy these extensive and severe lesions of general tuberculosis were found:

Brain.—The pia mater at the base was studded with fine, discrete, miliary tubercles. In diameter they were no more than the diameter of the shaft of an ordinary pin, and were difficult to see except where the meninges stretch across spaces, as at the optic chiasm and elsewhere. Along the vessels of the great fissures they were a trifle larger, thickly studding the membrane and gluing the folds to each other. In good light the ependyma showed the same-sized tubercles, still more difficult to see on account of the color of the surrounding tissues; ventricles not dilated. What was of most interest was a tubercular nodule in the right *flocculus of the cerebellum*. It was in size about a cubic centimetre. He regarded this condition as rare. In his somewhat extended experience in autopsies on tuberculous subjects, such tubercular deposits in the brain-substance had occurred but once or twice before, and never of the size of the specimen shown.

Lungs.—Both adherent throughout. Tubercular pleurisy on the left side. Bronchial glands extremely enlarged, cheesy, many of them fluid in centres, and a few wholly softened and fluctuating in their capsules. The lungs had a flabby, muscle-like feel, showing no tubercles on surface, but torn adhesions. On section, large, cheesy, rosette-shaped nodules were seen, varying in size from thirty to forty millimetres in diameter. These in appearance were much like the large tubercles seen on the costal pleura. Besides the discrete tubercles, there was also extended sclerosis and peribronchitis, probably made up largely or wholly of diffuse tubercle-tissue. Dilated bronchi, chronic and recent pneumonia, and œdema completed the picture of the lungs.

The *intestines* presented an equally serious lesion. The mesenteric glands were enlarged to the size of an ordinary native hickory-nut, and grouped closely into a nodulated mass. These were cheesy and partly diffluent. The agminate glands of the ilium showed ulcers occupying the entire site of the original gland, having deeply overhanging edges. In most cases the glands were wholly destroyed; in a few the swollen, cheesy, and softened glands still remained.

The *liver*, still more unusually, showed a few doubtful tubercles on the surface. The organ was enlarged and fatty.

The *spleen* was almost normal. Normal in size or a little undersized. No tubercles to be seen on the surface; two to four doubtful millet-seed-sized tubercles found.

The *kidneys* showed two to five similar undoubted tubercles.

The striking peculiarities of the case were (1) the large tubercular nodule in the cerebellum; (2) the extreme size of the bronchial glands; (3) the extent of the lesion, and the size of the mesenteric glands; (4) the somewhat infrequent occurrence of ulcers of Peyer's glands in tuberculous children, and in this case the great extent and advanced state of the ulcers; (5) the absence of tubercle in the spleen—this organ is usually involved greatly in general tuberculosis; and (6) the fact that there was tubercular meningitis with such extensive tuberculosis of the thoracic and abdominal organs.

It was more common to find the meninges intact where

there was well-distributed early tuberculosis of the other organs. It was the common experience in children, as in adults, to find children of the negro race more subject to tuberculosis.

Microscopic examination showed tubercular tissue in the nodule of the cerebellum, and also in the intestines.

Dr. J. W. Roosevelt showed some microscopic sections which illustrated the effect produced by

A NEW STAINING-FLUID,

which he thought was especially adapted to micro-photographic work. It does not undergo any change after once combining with albuminous tissue. As at present used it consists of about twenty-five drops of a saturated solution of ferrous sulphate to an ounce of water, and fifteen to twenty drops of pyrogallic acid.

The Society then went into executive session.

Stated Meeting, March 23, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. G. C. Freeborn, from the Committee on Microscopy, reported on

THE SPINAL CORD

presented by Dr. J. F. Ridlon, February 9, 1887. The portion of the cord included between the second and seventh dorsal segments, measuring about seven centimetres, is transversely flattened, and has an increased consistency. In this portion of the cord there is destruction of both the gray and white matter. The walls of the blood-vessels are thickened, and the anterior portion of the dura mater thickened, and it also contains calcareous deposits. The cord, above and below the compressed portion, shows the usual lesions of secondary degeneration.

The President presented a set of specimens accompanied by the following history:

EXTREME CIRRHOSIS OF LIVER, WITH CHRONIC PHTHISIS, CHRONIC DIFFUSE NEPHRITIS, AND TUBERCULAR PERITONITIS.

He was indebted for the epitomized clinical history of the case, and the report of the autopsy, to Dr. Ely, house-physician, First Medical Division, in Bellevue Hospital.

A married Irishwoman, forty-two years of age, came into hospital, January 27, 1887, with a history of morning sickness, anorexia, and nausea for five months. About Christmas there was abdominal distention, and she was tapped. After this the feet swelled and she had a slight, dry cough. On account of procedentia of long standing she has had painful micturition. Of late urine has been scanty. She has had spots before the eyes. She had no rheumatism; a good family but a marked alcoholic history. She was on admission anæmic, had œdema of the feet; the abdomen was distended with fluid, and the veins were enlarged. There was at both apices, behind, slight dulness, prolonged and high-pitched expiration, with exaggerated voice. The liver was small, extending from fourth rib to about one and a half inch from free border of ribs. Urine was 1.008; trace of albumin; fifteen ounces in twenty-four hours. She was tapped again on February 8th, and twenty pints of clear serum withdrawn, the catheter being left in for continuous drainage until the 13th. There was no more marked accumulation of fluid, but the patient became delirious, gradually failed, and died of exhaustion on March 21st.

At the autopsy twenty ounces of clear serum was found in the abdominal cavity. There were omental adhesions, miliary tubercles, and a little fibrin over peritoneal surfaces. There were tubercular ulcers of the small intestine. Kidneys: Capsule somewhat adherent; surface a little rough; cortex uneven, with obscure markings and yellowish streaks and patches (fatty degeneration). Spleen large and soft. Liver very small, weighing one kilogramme. Its surface is finely nodular, the small, projecting nodules being very yellow from fatty degeneration. The cut surface is rough, with broad and narrow bands of translucent connective tissue running between the islets of fatty parenchyma. There were partial adhesions of the lungs, which presented the lesions of general chronic miliary tuberculosis without cavities.

The anatomical diagnosis as already given was confirmed by the microscopical examination.

The President also presented a specimen

SMALL MULTIPLE ADENOMATA OF THE KIDNEYS.

A middle-aged man, without previous history, was run over by the horse-cars, receiving a severe lacerated wound of the leg, from which he died on the fourth day. The only noteworthy visceral lesions were those of the kidneys. These organs were small, capsules adherent, surface rough, cortex thin and rough, markings irregular. In the cortex of the right kidney was a white, dense mass about one centimetre in diameter at the broader side, wedge-shaped, and reaching from the capsule toward the medulla. The surface of the kidney at this place was slightly depressed. Projecting from different parts of the surface of the left kidney were five globular bodies—some white, others reddish-brown in color, and moderately firm in consistency, but less hard than the surrounding kidney tissue. These tumors were from seven millimetres to one centimetre in diameter, and were partly embedded in the cortical tissue. Although projecting from the surface of the kidney, the capsule extended over them. Several other small white and brown masses, looking somewhat like small, old, subcapsular infarctions, were scattered through the cortex of the left kidney.

Microscopically, all of the little tumors present alike the structure of adenomata. They consist of a moderately vascular connective tissue, stroma enclosing larger and smaller spaces. These spaces are mostly elongated, forming irregular tubules, which are either lined so as to form a lumen or completely filled with large cuboidal or polyhedral cells. The spaces in some parts of the tumors are larger and more irregular in shape, and are more or less completely filled with polypoid projections from the walls, covered with epithelium. The epithelium is in part finely granular, in part filled with small fat-droplets. The brown tumors owe their color to the deposition of blood-pigment in the epithelial cells, in the stroma, and in the kidney-tissue adjacent to them, and to undecomposed red blood-cells in the alveoli and tubules. While the larger tumors are sharply outlined against the adjacent kidney-tissue by a zone of squeezed and fibrous kidney-tissue, the smaller and apparently younger forms merge almost imperceptibly into the adjacent kidney-structure, so that intermediary forms between kidney and tumor tubules are readily made out. For the rest, the kidneys show the usual lesions of atrophied chronic diffuse nephritis.

Adenoma of the kidney is not of such infrequent occurrence as to be especially noteworthy; but this case is of unusual interest—first, because of the multiplicity of the tumors and their presence in both organs; second, because, microscopically, they show both of the structural forms which adenomata of the kidney may present, namely, the alveolar and papillary; and third, because of their uniformly small size.

PLEURO-PNEUMONIA IN AN INFANT.

Dr. J. Lewis Smith presented the thoracic viscera taken from the body of an infant that died at the age of eight months. Its parents were healthy. It did not present any marked degree of emaciation. About five weeks before its death an abscess formed in front of the left ear, which was opened, and discharged a couple of drachms of pus. The discharge from the abscess continued for nearly three weeks, when it gradually abated and soon ceased.

Two weeks before death the child became suddenly very feverish and restless, and vomited several times. Vomiting was not a prominent symptom after the first day and a half. From the sudden occurrence of the sickness, the temperature—104½° F. on the first day—and the rolling of the head, with more or less of twitching movements, the attending physician supposed that the case was one of *cerebral disease*. There was slight cough, and Dr. Smith discovered slight dulness over the apex of the right lung.

He did not see the child again until about a week afterward, when he was surprised to find complete dulness over the entire left lung, such as accompanies pleuritic exudation. The respiratory sounds were indistinct and distant, and faintly broncho-vesicular. The pulse was 180, respiration 76 to 80, and the apex-beat could not be detected. The temperature throughout was elevated; at one time 105½° F., and scarcely below 103° F. On the day of Dr. Smith's second visit the temperature had fallen to 101½° F. He was also inclined to the opinion that there was

PERICARDITIS WITH THE PLEURISY.

The autopsy revealed a nodule of pneumonic consolidation in the upper part of the right lung, with a small amount of fibrinous exudation along the free border of the upper lobe. On cutting into the lung immediately under the fibrinous exudation there were found seven or eight little spots of apparently necrotic tissue. When the left pleural cavity was opened, about two and a half ounces of sero-fibrinous fluid escaped, and the entire lung was covered with a plastic exudation. The lower lobe of this lung was almost completely hepatized by pneumonia. The superficial portion, besides, appeared to be in the condition of necrosis. The bronchi, the trachea, and the larynx showed only a very slight redness of the mucous membrane. Dr. Biggs had examined the specimens, and expressed the opinion that the pulmonary consolidation was probably of septic origin and secondary to the abscess. The heart was normal. The other organs were not examined.

The specimen was referred to the Committee on Microscopy.

Dr. H. J. Boldt said that he had made a sufficient number of post-mortem examinations in children who had exhibited marked cerebral symptoms with pneumonia to convince him that cerebral disturbance was of very frequent occurrence, and was of no special pathological importance.

Dr. Smith said that marked cerebral symptoms frequently occurred with the development of

PNEUMONIA AT THE APEX OF THE LUNGS IN CHILDREN.

Dr. W. M. Carpenter believed that marked cerebral symptoms were so frequently the precursor of pneumonia in children that a failure to examine the lungs was inexcusable.

Dr. Mary A. Dixon Jones presented a series of ovaries, the seat of

CHRONIC OVARITIS, WITH CIRRHOSIS AND MORE OR LESS DISEASE OF THE FALLOPIAN TUBES.

The histories of five cases were read in which she performed laparotomy for the removal of these organs. All the patients recovered, and were apparently benefited by the operation.

Case I.—S. S.——, aged twenty, a nurse by profession. When seventeen years of age she had a severe attack of Southern malarial fever, in consequence of which menstruation was suppressed for eighteen months. Since that time she has suffered with almost constant pain in the pelvis, greatly increased at the menstrual period; she was becoming incapable of attending to her duties, and more and more of an invalid.

The patient called to see her last December. On examination the right ovary was found enlarged, tender, and dislocated down into the Douglas cul-de-sac, and the left ovary was in position and apparently normal. The enlarged and prolapsed ovary was giving her almost continuous distress, and its evidently diseased conditions were affecting her general health and greatly disturbing her nervous system.

On January 20th she performed laparotomy and removed the right ovary and tube; the left ovary seemed all right and in good position, and she was glad to feel justified in leaving it. The incision in the abdominal wall was two and one-quarter inches, length of ovary two and one-half inches, transverse diameter one and three-quarters inch. The patient recovered without a bad symptom. The next day temperature, 90° F.; pulse, 84. Second day, pulse and temperature normal. The operation was to the patient much less trying than would have been the continued treatment, and the results would not have been obtained by it. March 17th, patient was the picture of health, vigorous, contented in mind, and able to work.

In examining the specimen, not a healthy Graafian vesicle nor healthy ovarian tissue was found.

Case II.—A girl, aged eighteen, came to the dispensary of the Woman's Hospital, pennyless and disheartened; said she had been turned from one situation after another on account of her frequent sickness and consequent inability to work; said her sufferings were indescribable, more than she could bear—pain, sick stomach, and a desire to go to stool when there were no demands of nature. The pain continued all the time, but the agonizing distress commenced some days before menstruation, and continued during the period. She was admitted into the Woman's Hospital of Brooklyn. Her sufferings during the next menstrual period were pitiful.

Examination.—Anteflexion, fundal enlargement of the uterus, and two sensitive masses on each side. Had tried many doctors and much medicine without relief. As soon as patient gained a little strength she removed the uterine appendages under thorough antiseptic precautions, or perfect cleanliness. There were considerable adhesions and some difficulty in removing the appendages. At the end of three days the patient was apparently well, had no more suffering, and now, March 16th, with a face beaming with happiness, she says, "she is glad she came to the hospital." She is now free from suffering and able to work.

The appendages were removed, not because she was suffering, but because they had such a condition of disease as to produce the suffering. Had they been healthy she would not have removed them on account of the great dysmenorrhœa, but would have labored to find out the cause of suffering and attempted to relieve it.

Case III.—Mrs. L——, aged thirty-six, married, no children; suffered with constant distress in the pelvis for the last thirteen years; great nervous disturbance. prostration, weakness, and inability to attend to her household duties.

Examination.—Ovaries enlarged and exceedingly sensitive, and dislocated low down in Douglas' cul-de-sac. For six months she was treated at the dispensary in hopes of relieving the tenderness, diminishing the size of the organs, and correcting the malposition. No special improvement in any of these respects. After consultation it was decided to remove the uterine appendages. The patient recovered from the operation without a bad symptom, and at the end of the third week she was able to assume the burden of her household duties. March 16th, called at the dispensary clinic, was the picture of health, suffering no distress, and able to work.

Case IV.—Mrs. M——, aged forty-three, has been suffering for many years; a confirmed invalid, in bed a great portion of the time, subject to sinking spells, at times remained unconscious for three or four hours, complained of great pain in the pelvis and bearing down. For the last five years has had at intervals severe uterine hemorrhages, and during the last five months has had a

constant flow without a day's intermission. Examination showed the uterus retroverted and retroflexed, and the fundus enlarged by an intramural fibroid, the appendages extremely sensitive and prolapsed. Laparotomy was performed March 9th. Uterus size of third month of pregnancy, ovaries atrophied, the tubes in a high state of inflammation, the veins of which were converted into great sinuses. At the close of the operation her pulse was 90. She recovered without a bad symptom; pulse and temperature normal.

The appendages were removed, first, because they were diseased; second, to cut off the blood-supply to the fibroid.

Case V.—Mrs. N——, aged thirty-one, married. The history of the last ten years has been a history of suffering—constant distress in the pelvis and in the back. Examination showed the appendages diseased, sensitive, and prolapsed. When she was taken into the hospital she was literally almost dead. She was kept quiet in bed, had good nourishment, massage, etc. March 14th, laparotomy was performed. April 2d, patient says she feels perfectly well. She recovered from the operation without a bad symptom.

Dr. Frank W. Jackson presented

A LIVER THAT HAD BEEN THE SEAT OF A GUNSHOT WOUND.

The patient was a male, thirty-six years of age, whose previous state of health had been excellent, except that for two months he had suffered from insomnia and mental depression. One Sunday morning he shot himself with a heavy revolver, carrying a long thirty-two ball, which passed through his white- and under-shirt, both of which it charred, and then entered the abdomen three-fourths of an inch below the tip of the ensiform cartilage, and half an inch to the left of the median line. He was immediately afterward found lying upon the floor. He was assisted to his feet, and he walked a distance of about thirty feet to his bed. He was then seen by a neighboring physician, who probed the wound apparently without antiseptic precautions. His own physician, Dr. Satterlee, saw him half-an-hour later, and found him in good condition, and with very little shock. In the afternoon Dr. Sands passed an antiseptic probe through the wound, three and three-fourths inches, in an antero-posterior direction, showing that the abdominal cavity had been entered. The ball was then found in the back, lying just beneath the skin, four inches below the angle of the scapula and one inch to the left of the spinal column.

THE QUESTION OF LAPAROTOMY

was at once discussed, but in view of the absence of the certainty of a wound of the stomach or intestines, and disinclination of the patient's friends to an operation, it was decided to wait for more definite symptoms. These never came. During the next week the patient's temperature was rarely above ninety-nine and a half, and he had absolutely no symptoms referable to the abdominal cavity. He had a short, hacking cough, and for four days after the injury there were physical signs of consolidation of the lung over an area of about the size of a silver dollar, heard just where the ball was lodged. He twice expectorated a small pellet of bloody mucus.

Seven days after the injury he was allowed to sit up for a while each day.

He did well for two weeks after this, when symptoms of mania came on; he finally became comatose, and after lying in coma for five days he died, just four weeks and four days after the shooting.

The autopsy showed that the peritoneal cavity was free of all evidence of the occurrence of general peritonitis, and there was no evidence that

BLOOD HAD ENTERED THE CAVITY.

Directly over the free border of the liver were found a few fine adhesions. There were also adhesions between the left lobe of the liver and the stomach. The stomach was otherwise intact. The liver showed a scar plainly, and the track of the bullet was traced directly through the substance of the left lobe, from before backward and from below somewhat upward. The ball then passed through the left crus of the diaphragm, and through the posterior mediastinum, but no evidence of wound of the lung was found. There were a few adhesions at the bases of both lungs.

The specimen was presented chiefly to show that the patient *did not die from gunshot wound of the liver.*

Dr. W. H. Porter reported an autopsy in which he found that a bullet had passed directly through the right lobe of the liver, just to the right of the gall-bladder, and there was absolutely no

HEMORRHAGE INTO THE PERITONEAL CAVITY.

The ball passed through the colon, and lodged in the vertebræ. The man lived two or three days after the injury, and died, apparently, from septicæmia.

In another case in which Dr. Porter made the autopsy he found that the bullet had traversed the liver, but there was no hemorrhage into the peritoneal cavity. He had also seen a case of rupture of the liver without hemorrhage.

The Society then went into executive session.

Correspondence.

OUR BERLIN LETTER.

THE SALARIES OF PROFESSORS—THE MEDICAL SCHOOLS AND SOCIETIES—PROFESSIONAL FEES—DEATH OF PROFESSOR HUBER—MUSEUM OF PATHOLOGICAL INSTITUTE.

Berlin, June 21, 1887.

The University of Berlin has 6,000 students, about 2,000 of whom are in the medical department. There are 44 medical professors, 57 docents, and 69 assistants.

Some of the professors of the medical department realize quite snug little sums from their teaching. Suppose, for instance, as is usually the custom, each student pays fifty marks ($12) per semester for his instruction. Say from one hundred and fifty to three hundred take a certain professor's lectures. He then receives $1,800 to $3,600 for his six months' work, which six months, omitting holidays and tardiness in beginning, is reduced to five months. For this, however, he lectures every day, or nearly so, sometimes twice in one day, and frequently two hours at a time. They depend more on their teaching, of course, and give it more time and attention. Many students do not pay cash, however. The professor gives him time to finish his course, get out into practice, and make the money to pay for his instruction. The student has not enough money to pay for his bier-kneipe, duelling expenses, and lectures too, so the latter is deferred. It is considered a debt of honor, though, and payment is seldom avoided. If the man dies and leaves nothing behind, the professor loses his money. For years afterward he receives frequent small instalments for a former semester's course of lectures.

The German lecture-room is a much more ceremonious place than with us. When the professor enters, all the students rise and respectfully bow, then resume their seats. The greatest quiet reigns during the lecture, and until its close. There are no late-comers or early goers, nor hooting, yelling, and other boyish pranks.

The student is required to attend nine semesters, four and one-half years, before graduating. Examinations are frequent, and he does not take up much at a time. There are several professors on each branch, and if he is expecting to be examined on that department he can spend almost the entire day in attending clinics and listening to lectures on that subject. The professor examines about four or six at a time, two or three times a week. The examinations are oral and clinical.

Berlin maintains ten medical societies: The Gesellschaft fuer Charité Aertze, Dr. M. Mehlhausen, president, Professor Henoch, secretary (seventy-six members, meets every two weeks); Gesellschaft fuer Geburtshülfe und Gynäcologie, Professor Olshausen, president, Dr. A. Martin, secretary (one hundred and forty-nine members, meets fortnightly); Gesellschaft fuer Heilkunde, Dr. Brock, secretary (one hundred and sixty-five members, meets annually); Gesellschaft fuer Naturwissenschaft und Heilkunde, Professor R. Hartmann, president, Dr. Bartels, secretary (fifty-two members, meets monthly); Gesellschaft fuer Psychiatrii u. Nervenheilkunde, Professor Westphal, president, Professor Bernhardt, secretary (ninety-two members, and meets monthly); Medicinische Gesellschaft, Professor R. Virchow, president, Professor B. Frankel, secretary (six hundred and fifty-two members, meets weekly); Physiologische Gesellschaft, Professor Du Bois Reymond, president, Professor Hirschley, secretary (one hundred and fifty-one members, meets fortnightly); Psychiatrischer Verein, Dr. Lehr, president, Professor Guttstadt, secretary (one hundred and twelve members, meets quarterly); Verein fuer Innere Medicin, Professor Leyden, president, Professor Paul Guttman, secretary (two hundred and thirty members, meets fortnightly). Vacations and holidays very greatly reduce the annual number of meetings. As will be seen, the Medicinische Gesellschaft is the leading medical society of the city. It meets in a fine large hall, with generally one hundred and fifty to two hundred members present, and is a power in the land. This society has a large library for the benefit of its members.

Berlin has thirty hospitals, containing five thousand beds; two thousand of these are in the Charité, by far the largest hospital in the city.

There are twenty-one institutions teaching midwifery in Germany.

The long, loud, and piteous wail from the Berlin correspondent of a Vienna medical journal, in a recent issue, over the number and increase of medical men in Germany, led your correspondent to study statistics, with the following results: Berlin has 1,150 physicians, 8.98 per 10,000 inhabitants—65 dentists, and 88 druggists. Prussia has 9,701, or 8.34 per 10,000 inhabitants—275 dentists—2,519 druggists—1,420 hospitals, with 72,308 beds. Germany has 15,783 physicians, 3.48 per 10,000—470 dentists—4,624 druggists—2,646 hospitals, with 128,306 beds. While these statistics show a low rate of physicians as compared with the United States, it gives a large number of hospitals and beds, which makes the difference. So many in Germany receive free treatment at the hospitals that there are fewer pay-patients left. Yet, I think, with the small number of physicians, they might get on without grumbling. What if they had one physician for every five hundred inhabitants, and old women were permitted to practise.

It may be of interest to American physicians to know a few of the legal rates allowed German physicians and surgeons for their work. Remember that a mark is a quarter, or about twenty-three and one-half cents: Light natural labor, 6 to 15 marks; twin, 9 to 24 marks; natural but tedious labor, day and night, 12 to 15 marks; foot presentation, 12 to 30 marks; turning, 12 to 36 marks; forceps, 12 to 30 marks; craniotomy, 30 to 60 marks; Cæsarean section, living woman—child alive or not—30 to 60 marks; same, dead woman, 12 to 24 marks; removal of unripe ovule or mole, 3 to 12 marks; examination of pregnant woman, 1.50 to 6 marks; writing a full report of case, 1.50 to 3 marks.

Surgery: Trepanning, 24 to 36 marks; strabismus, operation on one eye, 24 to 45 marks; both eyes, one-half more; extirpation epithelioma of the lip, 12 to 24 marks; second operation, one-half as much; enucleation of the eye, 12 to 36 marks; harelip, 12 to 24 marks; excision of the tonsils, 9 to 18 marks; removal of nasal polypus, 18 to 30 marks; catheterization, men, 3 to 6 marks; women, 1.50 to 3 marks; foreign body in the œsophagus, 6 to 12 marks; tracheotomy, 18 to 36 marks; excision of the breast, 24 to 45 marks; paracentesis thoracis, 15 to 20 marks; circumcision, 6 to 12 marks: castration, 30 to 60 marks; cut for stone, 60 to 150 marks; amputation, upper arm and leg, 24 to 45 marks; reposition, dislocated arm, 9 to 18 marks; setting broken collar-bone, 9 to 18 marks; neck of femur, 12 to 24 marks; blood-letting, 2 to 6 marks; assistant at operations, 3 to 9 marks; post-mortem, 6 to 12 marks.

Physicians' visits in the city: First two, 4 marks each; successive visit, with prescription, 1 to 2 marks. Patient one mile from city—first visit, 3 to 6 marks; each succeeding visit, 2 to 3 marks. Contagious fevers, charges doubled. Night-visits, first, 6 to 9 marks each; each following, 3 to 6 marks. Those between 10 P.M. and 6 A.M. are considered night-visits. Only two visits daily can be charged for; prescriptions in office, $\frac{1}{8}$ to $\frac{3}{4}$ mark. First consultation, 4.50 to 9 marks; each succeeding, 2.25 to 3 marks.

These fees, as may be readily seen, are very low; they are not followed closely, however, but are the legal fees, and are the amounts which may be collected by law. They have been in force since 1815, but usually these rates are exceeded.

As a contrast to these small figures we may now view some large ones. As nearly as your correspondent could ascertain, Professor Schroeder enjoyed from his practice an income of 250,000 marks annually; Gueserow, 150,000 marks; Martin, 100,000 marks; while Waldeyer, from his teaching, realizes 25,000 marks yearly. Martin has been known to ask, and receive, 4,500 marks for an ovariotomy.

Professor Emil Huber, of the Pathological Institute at Leipsic, died a few days since. Professor Huber was well known in former years to your correspondent, when Conheim's assistant. Many a dark subject has he made light for me. Always an enthusiast in his department, he was an indefatigable worker and a worthy teacher. He is called away in the midst of his usefulness, and will be missed in the medical world.

Dr. F. Mueller examined the fæces and the putrid active products of the urine of Cetti the faster, and reported to the last meeting of the Gesellschaft fuer Aertze. The products of the putrefaction of albumen in the intestines, iodol and phenol, developed the fact that the first was not discernible on the third day in the urine. The phenol sank up to the third day to quite a small quantity, but then increased to from three to seven times the usual amount. In experiments on animals the contrary has been observed. The sulphur in the urine, compared with the sulphuric acid, showed that the neutral sulphur did not maintain a comparison with the acid, but increased; also that a small portion of the sulphur oxidized to form sulphuric acid.

The urine showed the presence of acetic acid on the first day, in that it turned red, then black, upon the addition of chloride of iron. Acetone in large quantities was noticed in the urine on distillation. This is always seen in the urine in cases of severe disease, in marked cases of diabetes, in carcinoma, and with advanced cachexia. On the second fasting day the urine contained pepsin in large amounts. The speaker was therefore of the opinion that the urine contained albumen during the whole fast, but never grape-sugar.

On the eighth day the first stool was had; this was mostly from the last meal. Two hours after the first meal a stool occurred, the fæces of which came from the fasting period. Microscopical examination showed no remains of muscle-fibres or other nourishing matter. The field of vision was filled with numerous needles which consisted of sebaic acid. Spectroscopically, the hydrobilirubine streaks were noticed; also others which have not been described.

Dr. Zuelzer doubted if the light increase of carbonic and phosphoric acid in the urine was conducive to the theory that the change of bone-tissue was the real object

of the change of matter in starving organs. Experiments in the laboratory of the speaker had shown that in conditions where the bones are notoriously undergoing destruction, as in rachitis, this substance is most probably thrown out by way of the intestines. He was of the opinion that the carrying over of the phosphates into the urine, as he and others had observed in diabetes, was due to the co-operation of an agent which developed itself in the body—for instance, lactic acid.

Professor Virchow acknowledged that the source of the fat found in such quantities in the fæces might be in the bones. The examination of the bones in pernicious anæmia and other severe diseases had demonstrated that in these conditions the large long bones lost a great amount of their fat. Professor Virchow took this opportunity to call attention to facts which recent study of an artificial butter had given. In the time of Napoleon III. the first experiments were tried to produce a cheap substitute for butter. These originated from experiments which had been made on starving cows with regard to the composition of milk. From the moment nourishment was discontinued a change came in the milk which was only explained by the belief that bone-fat had been reabsorbed and thus appeared. It was quite possible the fat observed by Dr. Mueller in the fæces came from the same source.

The Museum of the Pathological Institute of Berlin has reached proportions which are remarkable. The office of custodian has hitherto fallen to the first assistant of Professor Virchow, and has been quite acceptably filled for the past fourteen years by Dr. Juergens. It has, however, grown to such dimensions as to demand a custodian especially appointed. It has increased from the union of two collections, that belonging to the Charité and a part of the Anatomical Museum of the University. The latter was separated from the Anatomical Museum in 1858, when an independent professor of pathological anatomy was first named. Professor Reichert, who was then director of the museum, clung to his rights so tenaciously that it was twelve or fifteen years before the preparations were removed, and then only in part. The entire collection was not removed until after his death. Part of these specimens came down from the earlier years of the last century. Of especial worth are the preparations left by Johannes Miller. It is the documentary evidence of his pathological anatomical work. The Charité collection, which was the groundwork of the museum, began to assume important proportions in the third decade of the present century. Its originator was Philip Phoebus, who was less known as pathological anatomist than by his labors in pharmacology and through his general usefulness. His industry has left us writings which remain to this day. He is particularly known in his dealings with the region of the heart. His successor was Robert Frossep. His most important work was not in the field of pathological anatomy either. Professor Virchow became prosector in 1846, and continued until 1849. The successors of Virchow were his friend Benno Rheinhardt, who, with Professor Virchow, originated the Archives of Pathological Anatomy, and Heinrich Meckel, of Heinsbach. Both died in early life, the victims of consumption. Meckel was the friend of the poet Lenabb, who died insane. Meckel examined his brain and published a carefully prepared report. In 1858 the museum was again put under Virchow's direction, and it continued to grow until it is one of the first of its kind both as to the number and worth of its specimens. Pathological anatomy is now the great incentive to a visit to Berlin. Virchow's reputation attracts students and practitioners from every part of the globe. It is true that the man is overrun with politics, the affairs of state, and his many other interests. His lectures can be read as well as heard. He is usually tardy, frequently absent, very cross and irritable, yet he has the reputation, and men crowd to his lectures.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE DEPOPULATION OF FRANCE—PROSTITUTION IN PARIS—THE PRESERVATION OF CORPSES.

PARIS, July 1, 1887.

In a series of debates that have lately taken place at the Paris Academy of Medicine, on the alarming extent to which the depopulation of France continues to increase, a commission composed of MM. Ricord, Bergeron, Léon Collin, Le Roy de Méricourt, Léon Le Fort, and Albert Fournier, was instituted to investigate the subject. One of the principal causes of this depopulation is attributed to infant mortality, which seems to be on the increase, owing chiefly to the premature feeding of infants, and to other circumstances incidental to their being separated too early from their mothers and put out to nurse. But another cause of this great mortality among infants is attributed to hereditary syphilis, and in a very remarkable and lengthy report by Professor Fournier, which was recently read at the Academy of Medicine, the celebrated syphilographer proposes, among other means to prevent the extension of this affection, that the most rigorous measures should be carried out to put down what he terms clandestine prostitution, a term employed in contradistinction to authorized prostitution which is sanctioned by the Government and subjected to the strictest surveillance of the police. This clandestine prostitution is practised in various ways by women and girls little suspected of such a vice, to say nothing of those employed in shops, hotels, and public houses. Dr. Fournier's most erudite report is too elaborate to be reproduced here, but it deserves the most careful perusal by all concerned with the public health, which, in this country at least, is in permanent danger owing to the prevalence of what is appropriately termed "the modern plague," and which is none other than syphilis. The reporter admits the difficulties one must encounter in seeking a remedy for this state of things. He thinks this could be done by making the regulations respecting registered prostitutes more stringent than they have been. In the first place, they should be held under strict medical supervision, and instead of a visit bi-monthly for free prostitutes, and weekly for those domiciled, all, whether free or domiciled, should be subjected to a weekly visit by a medical man, and to a supplementary visit once a month by a medical inspector at an unfixed date. Each of these visits should be complete, and should be directed principally to the examination of the genital organs, and of the mouth. He recommends also special hospitals for the treatment of venereal diseases.

In the first edition of his treatise on "Descriptive Anatomy," Dr. Bouchard, Professor of Anatomy at the Faculty of Bordeaux, published a receipt for the preservation of corpses. He has since perfected his method, and in a formula given below, which he lately submitted to the Paris Academy of Medicine, he believes that a corpse may be preserved for an indefinite time, even at a high temperature, without altering its composition or modifying the structure of its anatomical elements: Borate of soda, hydrated to 10 equivalents of water, 10 kilogrammes; glycerine at 30° Baumé, 17 kilogrammes. The borate of soda, after having been reduced to a very fine powder, should be put into a vessel, and then made into a mixture by pouring glycerine slowly on it. The whole should be heated to a temperature of about 80° C., until the solution becomes complete. Finally, the solution should be strained through flannel. In this state the mixture is syrupy, and as it is somewhat thick for injecting, a little alcohol is added to it to render it more liquid. The injection is practised in the carotid or the femoral arteries. For dissected subjects the four extremities should be injected. Besides this preservative power of the liquid, it has the great advantage of rendering dissecting wounds inoffensive, and Dr. Bouchard stated that since the employment of this liquid, he has

had no cases of gastro-intestinal troubles among the medical students, which before its introduction were of frequent occurrence among them.

In continuing his researches on the therapeutics of morphinomania, already reported in THE MEDICAL RECORD of June 11th, Dr. Jennings read a paper at the Medical Society of the Arrondissement of the Elysée, on "The Inhibition of the Want of Morphine by the Use of Nitro-glycerine associated with Sparteine." Dr. Jennings finds that the one is a powerful adjuvant of the other, and as the action of the former is rather transitory, he recommends that the one should not be employed without the other, though not necessarily simultaneously. According to his experience, however, he found that the simultaneous administration of the two medicaments was preferable, the one (sparteine) in hypodermatic injection, the other by instillation on the tongue or in the form of pastilles. With these two drugs we possess, according to the author, a means of the first order to combat the feeling of the want of morphine in its double modality. In concluding his paper, which has also been published in the form of a pamphlet, Dr. Jennings explains that the sensation of the want of morphine is of complex origin, cerebral and peripheric, each element of which may be combated by appropriate medication. The organic weakness is counteracted by the sparteine, which raises the action of the heart in the morphinomaniac during privation, similar to what takes place after an injection of morphine. The cerebral suffering, often the most painful, and which responds to a particular want of habitual congestion, is arrested by nitro-glycerine. For morphinomaniacs in privation, this medicament recalls, by the sensations to which it gives rise, the effect of a hypodermatic injection. As to the intimate mechanism of relief, Dr. Jennings sees in it a phenomenon of inhibition by an action at a distance more than by an essential sedation of the nervous centres.

At a recent meeting of the Paris Municipal Council, it has been proposed that hospitals for the exclusive treatment of infectious diseases should be erected outside the city. This measure is considered preliminary to the removal of all hospitals from the town, reserving smaller establishments only for the treatment of urgent cases.

Dr. Albert Robin, an Agrégé of the Faculty of Paris, has been elected a member of the Academy of Medicine, of which he is the youngest in age, he being only about forty years.

Professor Bouchard and Professor Verneuil, both of the Faculty of Paris, have been recently elected members of the Academy of Sciences, in the Section of Medicine and Surgery.

THE FEE FOR A CASE OF GONORRHŒA.

To the Editor of The Medical Record.

SIR: The fee-bill attached to my pocket-record gives $20 as the amount to be paid the physician as a retainer in a case of gonorrhœa, and states that subsequent charges are to be graduated according to circumstances.

County medical societies pretend to regulate the fees for ordinary operations, specific treatments, etc., but their schedules are, like the weather, subject to marked variations. Custom, however, has established one inexorable law, namely, that when advice and treatment are sought, something in the shape of money is to be given to the adviser as preliminary to obtaining his services, and when it is not forthcoming he is at liberty to say what the said services are worth. Very few patients have the manliness to pay for what they get after recovery is once established, but this is not to be wondered at. The source being dishonest, it is not in human nature to be made honest by passing through an affliction which is notoriously tedious, painful, and disgusting.

Once upon a time a physician was consulted by a young woman who complained of having violent headaches. Being thoroughly acquainted with her character and history, he located the seat of the trouble in the genitalia, and in the course of a few minutes' conversation received satisfactory answers to leading questions, and made a diagnosis of gonorrhœa. An examination with speculum was not deemed necessary, for the simple reason that it is impossible to suppose a female so lost to decency and modesty as to claim to be so diseased falsely.

Even hysterical patients draw the line at "the bad disorder." Hot astringent injections were ordered, and the patient placed upon tonic treatment, tr. ferri chloridi.

The girl was earning her own living, and it was mutually agreed that a large fee would not be demanded, because, as she ingeniously claimed, she was the victim of some man's villainy. Such arrangements are perfectly legitimate, although it is not safe to admit a plea of that kind, for the attendant may find himself confronted with a fact stated in its naked truth by a female, as the writer once was. A young woman who had gonorrhœa for sale applied for treatment, and claimed that she had been the source of so large a revenue that she deserved medical attention gratis.

The patient first mentioned went about her business, and the incident had escaped the physician's memory, when it was recalled by the application for treatment of her employer, a young married man. His story was not a straightforward one at all. He had been lifting trunks at his establishment, and had strained his back, which had led to a chill, and these symptoms were in turn followed by a discharge from the penis. The existence of the purulent discharge was at first strenuously denied, and an inspection of the genital organs refused until he was confronted by testimony obtained from his washerwoman. He was perfectly satisfied to undergo whatever treatment was thought necessary, and did follow out the rules laid down to the letter. One thing of importance he neglected, and that was to pay for what he received. After a short interval he was advised to take a vacation for his health. This step was thought to be necessary, for the simple reason that while he attended to his work he was constantly in the company of the young woman referred to previously.

About the time he was ready to leave home, a young man employed in his establishment came to the same physician and asked for treatment for gonorrhœa, and told without any hesitancy where he had picked it up.

A wayfaring man, though a fool, would hardly question the physician's diagnosis of these cases under the circumstances, but, to his utter astonishment, when after the lapse of a month a reminder was given to them, they denied having received the services for which pay was demanded.

There had been a money-transaction between the physician and one of his patients prior to this time, and the latter held a note bearing the former's signature. An attempt to collect the bill was threatened with a foreclosure of the obligation. But the note having been paid, suit was entered against the two men for $50.

At the hearing the plaintiff, defendants, attorneys for both sides, and two physicians summoned as experts (?), were locked in the office of a justice of the peace.

One of these physicians testified that he treated one of the defendants for *uric acid* about one month before the date of first treatment for gonorrhœa. When asked for his prescriptions, he stated that he had *told* his patient to take lithiated hydrargea; also said that it took a month to effect a cure of *uric acid*. According to his testimony, it was customary for the patient with gonorrhœa to pay $10 in advance, and the medical attendant was bound to render any further services for nothing. He said he once received a fee of $50 for treating a case of gonorrhœa, but he did not make such a charge; he only took it because it was offered to him.

The same man said that the second defendant could not have had gonorrhœa, because he had phimosis.

The second physician testified that his fees for gonorrhœa ranged from two to ten dollars; also that gonorrhœa only affected the head of the penis. Notwithstanding the admission of one of the defendants that he lied to his physician when he applied for treatment, judgment was entered against the physician in both cases.

The suits were appealed. In the meantime, a warrant for the physician's arrest was put in the hands of the sheriff, and a bond of $1,000 required for his appearance at court to answer a charge of slander.

Such law was too wonderful for the physician, and he allowed proceedings to drop, and a like termination came to the suit for slander.

One thing more may be of interest to any who should ever find themselves placed in similar circumstances.

Both the men mentioned went to the same locality during their treatment. Having ascertained the name and address of each druggist in this town, a request for copies of his prescriptions was mailed to each. Courteous replies came in due time from all but one firm, saying that such prescriptions were not on file. A second letter to this house, couched in the following language, failed to elicit a response.

"Sirs: Some time ago I wrote to you for the purpose of obtaining information in regard to two prescriptions which I had reason to suppose were on file at your drug-store. Up to the present time no reply has been received. The request for copies of my own prescriptions is unusual, but the circumstances under which it was made are equally so, and in renewing that request I desire to make some explanation of the facts which render it of importance to me to obtain what is asked for. In July —— I treated two young men and a girl for gonorrhœa. One of the men was a former resident of —— and spent a fortnight in that place while undergoing treatment; during that time he had my prescriptions filled at one of the drug-stores there—so he told me after his return. The other druggists have informed me that their files do not contain duplicates of the enclosed prescriptions, and it is therefore concluded that they are on file at your establishment. My attempt to collect my bill is now met with the cry of thief, liar, coward, and blackmailer, and as a last resort with a suit for slander. Now I know that it is the duty of the pharmacist to shield his patrons, but at the same time I do not believe you regard it as necessary to countenance such an attempt to injure a physician."

J. E. Free, M.D.

Harrisburg, Pa.

THE CENTRES FOR SIGHT AND HEARING.

To the Editor of The Medical Record.

Sir: Permit me, through your valuable columns, to ask the assistance of our learned profession in the settlement of a question that is now under discussion and consideration by the Neurological Society of London, viz.: "The localization, in the cerebral cortex, of the centres presiding over sight and hearing."

In a somewhat lengthy and careful series of experiments upon monkeys, recently made at University College, London, by Professor E. A. Schäffer and myself, with the purpose of throwing some light upon the subject, we uniformly obtained results directly opposed to Ferrier's views, as set forth in his last edition of "Functions of the Brain," viz.: That the centre for hearing, in one ear, is in the superior temporo-sphenoidal convolution of the opposite side, and that for sight, in one eye, in the angular gyrus of the opposite side.

Now it appears that some seventeen cases of cortical lesion in the human subject have been collected which seem to support Ferrier's conclusions. Without questioning the reliability of these cases, I must suggest that unilateral defect of both sight and hearing is very common when not due to cortical lesion, which would, to a considerable extent, tend to bring the above-mentioned cases within the range of coincidence, while a case of lesions in these situations, without defect of sight or hearing, would not be open to this objection.

Though it is a less cheerful task to publish evidence destructive of an ingenious theory than to furnish facts in its favor, the interests of science demand that as much zeal should be displayed on the one hand as on the other.

Hoping, Mr. Editor, that The Medical Record and the profession at large may not lose sight of the fact that it is even of more importance to carefully examine and report a case of cortical lesion in which, during life, there has been no disturbance of function than one wherein such disturbance may have existed,

I remain, yours very respectfully,

Sanger Brown.

163 State Street, Chicago, June 23, 1887.

[Reports of cases such as Dr. Brown suggests are certainly desirable. It should be stated, however, that Dr Ferrier no longer holds the angular gyrus to be the sole centre of vision, while many observers have contributed more than Ferrier to show that the first temporo-sphenoidal convolution is in relation with the function of hearing.—Ed.]

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 3 to July 9, 1887.

Tremaine, William S., Major and Surgeon. Ordered for examination by Army Retiring Board, at Governor's Island, New York Harbor. S. O. 151, A. G. O., July 1, 1887.

Skinner, J. O., Captain and Assistant Surgeon. Granted leave of absence for four months, on surgeon's certificate of disability. S. O. 151, A. G. O., July 1, 1887.

Harris, H. S. T., First Lieutenant and Assistant Surgeon. Will be relieved from duty at Fort Ringgold, Tex., upon the return of Assistant Surgeon W. F. Carter, and will then report to commanding officer at Fort McIntosh, Tex., for duty. S. O. 73, Department of Texas, June 27, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 9, 1887.

Hudson, A., Medical Inspector. Detached from the Trenton and wait orders.

Scofield, W. K., Medical Inspector. Ordered to relieve Medical Inspector Hudson on the Trenton.

Coleridge on the Subjective Side of Jaundice.—In a letter from Coleridge, recently found and published, he says: "I have felt unwell and depressed by day and wandering all night through the Swedenborgian Devildom, like a Dante all at once left by his guide, or whose supposed Virgil had turned into Mrs. Brownrigg. While I remained quiet and motionless I had full possession of my thoughts, but as soon as I attempted to give them utterance I became flurried and lost all command over them. The cause and occasion of all this distemperature were at length disclosed, and on commencing my morning shave, the only time I have the pleasure of looking at myself, I was greeted by a duplicate (in color though not in stature) of Nebuchadnezzar's images. From the hair-line of my forehead to the soles of my feet all gold, with some alloy of brass or copper for the neck and breasts; in short, a consummated jaundice."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 9, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	11	5
Scarlet fever	26	7
Cerebro-spinal meningitis	4	4
Measles	22	4
Diphtheria	92	34
Small-pox	5	2
Yellow fever	0	0

The Niagara University at Buffalo, in conferring its degrees "hoods" its candidates, in pursuance of an ancient custom. Instead of the Hippocratic oath a special formula is used, taking "*religio, mores, cultura*" as the motto.

Prostitution and Insanity.—At the first (Moscow) congress of Russian alienists, Dr. Prascovia N. Tarnovskaia, of St. Petersburg, communicated (*Vratch*, No. 9, 1887, p. 216) the results of the anthropometric examination of fifty habitual prostitutes, who had all been inmates of brothels for a period of not less than two years. For the sake of comparison she examined in the same way fifty peasant women of the same age, and as far as possible of the same intellectual development, etc. The results of this — probably unique — investigation may be summed up as follows: 1. The prostitutes presented a shortening, amounting to half a centimetre, of the antero-posterior and transverse diameters of the skull. 2. As many as eighty-four per cent. of habitual prostitutes showed various signs of physical degeneration, such as irregularity in the shape of the skull, asymmetry of the face, anomalies of the hard palate, teeth, ears, etc. 3. In eighty-two per cent. of the prostitutes the parents were habitual drunkards. 4. In eighteen per cent. of cases the prostitute examined was the last survivor of a large family of eight to thirteen children, all of whom had died at an early age. 5. These facts afford ground for the belief that prostitutes, as a class, furnish the largest contingent of subjects predisposed to nervous and mental affections. There is no special work in any language on this subject, nor are there any statistics as to the number of prostitutes yearly admitted to asylums. Dr. Tarnovskaia urges the desirability of collecting such statistics for the purpose of determining the part which professional prostitution plays in the causation of mental and nervous disease.—*British Medical Journal.*

The Dose of Antipyrine.—Dr. Herman Ostrander, of Lansing, Mich., writes that he has used antipyrine very extensively in his practice for more than a year, and has never failed to get the desired result with five-grain doses, repeated every hour until fifteen grains were taken. He has never exceeded thirty grains in twenty-four hours. He adds that he can corroborate what has been said as to its use in migraine, and is also sure it will relieve pain of rheumatism.

Plurality of Urinary Albumens.—Dr. Lucas-Championnière observes that it is now known that the albumen which is found in the urine is not single, that its constitution varies, and that the presence of these different forms of albumen may imply also a different prognosis. He quotes as follows from the recent works of M. Jaccoud: We may say to-day that there are three kinds of albumen to consider in pathological urine. First: Serine. This albumen is identical with that of the serum of the blood; it is the albumen most distinctly pathological, if we may say so, the albumen of Bright's disease; there is no Bright's albuminuria without serine. Second: The numerous family of globulins, paralbumen, metalbumen, of which the most ordinary type is paraglobulin, again called simply globulin. Third: The peptones, which correspond to the ancient albuminose of Mialhe. Now, from the examination of facts it results that, of these three forms of albumen the first only, serine, is related to a lesion of the kidney; globulin and peptone are not dependent upon lesion of the kidney, but must rather be referred to a peculiar state of the albuminoids of the blood. There is great practical interest in this, for globulin precipitates by all the reactions which are commonly employed in the study of albuminuria, and its presence may consequently lead one to believe in a renal lesion which does not exist, or, if it co-exists with serine, may cause one to suppose that a present albuminuria is much more abundant than in reality it is. As to peptone, that does not precipitate by the usual reagents for serum-albumen, and its presence in the urine does not give place to any error in this respect. The only difference that can be noted between the precipitates given by the two albumens are the following: With globulin the coagulation is a little slower, it is not absolutely instantaneous like that of serum-albumen; moreover, the precipitate, however abundant it may be, is never flaky at the moment of its formation, it does not become so secondarily, and does not present the phenomenon of retractility. These facts are important, for the slowness, the homogeneity, the absence of flaky divisions, and its retractility are precisely the characteristics of albuminous precipitates which are observed in the transient albuminuria, notably in the course of and following acute diseases; and inasmuch as, even of late, the precaution is not taken to separate the globulin before treating the urine with the ordinary reagents, it is probable that in most of these cases there has been found a globulinuria and not a serum-albuminuria, that is to say, in fine, a false albuminuria due to a transient modification of the protein substances of the blood under the influence of acute diseases. The process for the separation of the two kinds of albumen is very simple. A saturated solution of sulphate of magnesia is prepared, the saturation being such that some crystals are left undissolved. To a given quantity of urine an equal quantity of this solution is added, and the mixture is kept cold for twenty-four hours. At the end of this time an opaque cloud has formed by the precipitation of globulin. This substance is coagulated fully, and is pure, without admixture with other albuminoids. The coagulum so produced is separated by filtration, and in the filtered liquid one can test without fear of error by the ordinary reagents for serum-albumen.—*St. Louis Courier of Medicine.*

Acute Melancholia Caused by Impacted Fæces.—Hutchinson (*American Journal of Insanity*) has detailed a case of this kind occurring in a married woman of forty. At the time of her admission into the Western Pennsylvania Hospital for the Insane, the patient suffered from acute melancholia, was very weak and extremely emaciated, her skin was bronzed, dry, and harsh, her hair was dry and falling out, and all the secretions of the body were perverted. On examination, a distinct tumor could be felt through the abdominal walls, following the course of the rectum and sigmoid flexure, and making the introduction of a catheter to relieve the distended bladder almost impossible. The tumor was thought to be an accumulation of hardened fæces. Accordingly, the scoop and appropriate injections were employed for several days, with the ultimate result of removing the mass entirely. Rapid improvement in the patient's health, both mental and physical, followed this evacuation, so that in less than one month she was discharged, being then in the enjoyment of perfect health of body and mind alike.

Juvenile Intermittent Albuminuria.—Considerable interest attaches to cases of cyclical albuminuria, for their pathology is unknown, and perhaps is different in different cases. The causation of mere intermittency of symptoms generally has not received adequate attention. M. Teissier has collected a fresh series of ten cases of cyclical albuminuria. He lays stress on the following features: A separation of oily matter on the urine, and the presence in it of brilliant bluish or metallic looking spangles; the absence of true casts, though cylindroids, possibly of mucus, and sometimes drops of fat, may be detected with the microscope; the slightness of the subjective symptoms, which may consist of mere vague feelings of malaise, of pain in the back, of weakness, or of pains in the limbs. Neuralgic troubles are rare. There is great nervous excitability or impressionability. Physical examination has never revealed the "bruit de galop." The lowness of arterial tension, which is calculated to be equal to a column of mercury sixteen to seventeen centimetres high, is important as an item in the differential diagnosis of cyclical albuminuria from interstitial nephritis. Dilatation of the stomach was observed in three cases. Three patients had had eczema or urticaria. Neither œdema nor "dead fingers" was noted. Speaking generally, the aspect of the patients is one of good health. The complaint, if such it can be called, is commonly curable; but slight relapses may recur under the influence of fatigue or violent impressions. The age that is most liable to the affection is ten years from puberty onward; males suffer more than females. Violent exercise and excessive emotional excitement are direct causes. Teissier does not accept the mechanical theory of Bar, nor the theory of disturbance of the glomerular circulation of Magnin. His own view, propounded two years ago at Grenoble, he now believes to be insufficient to explain all the phenomena. A slowing of the combustion of albumens will not explain the presence of fatty matters or the increase of urea in the urine. His present position is to regard the malady as due to over-action of the liver, which is the factory for urea, uric acid, and fatty matters. In treatment the importance of hygiene is very great. These patients are perhaps predestined to become gouty. Shampooing, plenty of fresh air, prohibition of alcohol and white wines, and moderate exercise, are to be prescribed for these young men. Arsenic, inhalations of oxygen, cold baths, bromides and hydrotherapy, tannin, benzoate of soda, etc., are recommended, but especially sweet spirits of nitre, twelve to fifteen drops a day (alcool nitrique); milk, eggs, and ham may be eaten, but not fish; thermal waters are good.—*The Lancet.*

Pasteur Defends Himself.—At a recent meeting of the Imperial Society of Physicians, a letter from M. Pasteur, in Paris, was read, in which he defends himself against the imputations made against his system by the Vienna professors, especially Prof. Billroth, who pronounced the vaccination of hydrophobia a fiasco.

An Overdose of Eserine.—Dr. Dunlop has reported the following case in the *Lancet:* A lady of about sixty years of age, who had slowly advancing cataract in the left eye, and incipient disease of the same kind in the right, began, early last October, to suffer from irritation of the conjunctivæ. The eyes were suffused and the conjunctivæ often somewhat injected, and the discomfort was increased by fatigue, exposure to cold, or strong artificial light. The patient consulted an oculist in London in November, and a variety of constitutional and local remedies were employed without any very satisfactory result. On January 19th the use of eserine was advised, with the view of lessening the amount of light passing into the eye. Accordingly a solution of the strength of one grain to the ounce was prescribed, and a drop was ordered to be placed in the eyes twice a day. At about 4 30 the same afternoon the first application was made, and a small drop of the solution placed in each eye. A good deal of smarting and lacrymation followed, and as this passed off, in about a quarter of an hour severe clonic spasm of the eyelids set in, the upper eyelid, as the patient described, falling down on the lower every few seconds. About a quarter of an hour later a feeling of spasmodic stiffness in the lips, especially the upper, set in, and soon there was the same sensation under the jaw on the left side. Within an hour there was a feeling of tremor or spasm, but without any actual muscular movements in the arms and thighs, and at the same time there was a sensation of pressure on the eyeballs and of weight and pressure within the head. The patient also began to suffer from some mental confusion, and her memory was impaired. By 11 P.M. the movements of the eyelids had diminished considerably, but the other symptoms had altered very little. She slept uneasily, waking at frequent intervals during the first part of the night, and when she awoke was conscious of the same sensation, though in diminishing degree. In the morning the muscular sensations had disappeared, but she felt weak and shaken. Dr. Dunlop saw her a little before noon on the 20th, when he found the pupils contracted to a fine point, and the conjunctivæ a good deal injected. All the spasmodic muscular feeling had disappeared, but she complained of the pressure on the head and on the eyes. She said there was some mental confusion and a general feeling of weakness. Next morning, the 21st, the pupils were still minutely contracted, and as she still complained of the pressure on the balls, he ordered a weak atropine lotion. On the morning of the 22d, before using the atropine, the weight in the head and the pressure on the eyeballs passed off, and she felt stronger and better. A visit to the druggist who dispensed the prescription fully explained the matter, however, for it appeared that by mistake he had made the solution of the strength of one grain to the *drachm* instead of one grain to the *ounce.*

The Antiquity of Trephining.—Antiquarian research sometimes produces curious and unexpected results. A short time since a dental surgeon made it his business to examine microscopically the teeth in some pre-historic skulls, and as a result thereof was able to determine the food on which the owners of the said skulls had subsisted. Professor Horsley has also occupied himself with ancient skulls, and judging from the marks found on them, concludes that the operation of trephining is by no means modern. He has extended his researches in this direction, and recently read a paper on the subject at the Anthropological Institute of London.

Expulsion of the Uterus during Labor.—Dr. Francisco saw the following case in consultation: A primipara, aged twenty-three, feeling the pains of labor beginning, sent for a physician, who examined and found the vertex presenting. The pains continued satisfactorily, when suddenly, after an intense pain, the whole womb with the child in it was expelled from the vulva, carrying with it the vagina. The cervix lay only two or three fingers' breadth above the knees of the patient. The os was only dilated to about the size of an English shilling, and was very rigid. While the doctors were consulting, the patient had two pains, and the child was born; two deep lacerations having taken place on the left side of the os tincæ. The cord being tied, and the after-birth and membrane extracted, the womb and vagina were carefully replaced and a binder applied. The temperature marked 101.3° for the first two days, then became normal, and the patient made a capital recovery. The child was a female, living, and appeared of full time and strong.

Illegitimacy as a Cause of Idiocy.—Dr. A. Mitchell has collected a large number of statistics bearing on the question of idiocy, and comes to the conclusion that illegitimacy is a very prolific cause of this condition. He believes that the mental agony suffered by the unfortunate mother reacts upon the fœtus, causing an arrest of development and occasioning congenital idiocy.

NEURO-MYOLOGY:

CLASSIFICATION OF THE MUSCLES OF THE HUMAN BODY WITH REFERENCE TO THEIR INNERVATION, AND NEW NOMENCLATURE OF THE MUSCLES.

BY ELLIOTT COUES, M.D.,

PROFESSOR OF ANATOMY, NATIONAL MEDICAL COLLEGE;

AND

D. K. SHUTE, M.D.,

PROSECTOR OF ANATOMY, NATIONAL MEDICAL COLLEGE.

INTRODUCTORY.

A NERVE may be defined as a line of least resistance to motion in a living organism. A sensory or æsthesodic nerve is one which transmits certain modes of molecular motion from without inward, or from the locomotorium to the sensorium of the organism. A motory or kinesodic nerve is one which transmits a certain mode of molecular motion from within outward, or from the sensorium to the locomotorium of the organism. A motory nerve is the means of translating molecular into molar or mechanical motion; a sensory nerve reverses this process. Most nerve-tracts are sensorimotor, acting both ways.

A muscle may be defined as a line of least resistance to the motor influence of a nerve. Muscle is next most kinesodic after nerve. This is the tissue in which the cumulative effect of molecular motion in nerve is immediately translated and manifested in molar movement. A voluntary muscle is one from which motor influence can be withheld at will. An involuntary muscle is one from which such influence cannot be thus withheld.

The simplest case of muscular motion resulting from nervous influence is when one part of a single cell moves mechanically in consequence of a sensation in the other part of the cell. The ciliary vibration of a ciliated epithelicell is a case in point: for this implies the translation of sensation, which is a vital mode of motion, into ordinary mechanical movement. All transfer of motion along any line of least resistance, as a nerve, to another line of next least resistance, as a muscle, is no more than the extreme amplification and elaboration of the simple case cited. Motility is the prime characteristic common to nerve and muscle; it shows their relation to be immediate and their connection to be the closest possible

The whole nervimuscular system of an animal maintains this close connection, which is not less intimate when myriads of cells stand in such inter-relation than when two cells, or two parts of one cell, are thus interdependent. Nor is the case altered if, as usually happens, nerves remain slender threads while muscles become bulky masses. For muscle is only an aggregate of filaments as fine as nervous fibrils, and both are cells in ultimate analysis. In point of fact, the total motility of a nerve-tract exactly equals that of the corresponding muscle-tract; the motor power of nerves being in every case nicely adjusted to the resistance which can be overcome by muscular action.

No muscle is developed except in connection with some nerve, and every muscle sustains the character of an instrument of some nerve. From an anatomical as well as a physiological stand-point, upon genetical as well as functional grounds, nerve and muscle are inseparable.

It appears, then, that the whole muscular fabric is built upon the plan of the nervous system. It follows that the clew to the organization of the muscular system, and consequently the rational classification of the muscles themselves, is found in the disposition and arrangement of the nerves. Neurology is the key to myology; and a neuro-myology is practicable.

The coming neuro-myology is forecast in outline in the present article, which offers to classify and name the voluntary muscles of the human body according to the nerves which severally supply them with motor power. We only compromise the matter here and there, in order to disturb the text-book order of things as little as possible. For the present we would rather evade the full consequences of our audacious iconoclasm than lay too violent hands upon the venerated relics of anatomical antiquity. There is too much rubbish to get rid of all at once, and the very cobwebs that cover the bogies in the garret are dear to our hearts. So the new arrangement of the muscles is not quite off with the old love. But we make bold to attack the *names* of muscles with all our might. There is no reason why a muscle should be called *levator labii superioris alæque nasi*, except that it has been called so; and it need not be called so any longer, if calling it *nasi-labialis* will be better. Why must generations of students be compelled to talk of an *abductor ossis metacarpi minimi digiti* and a *musculus accessorius ad sacro-lumbalem*, because some old anatomist described certain muscles in that way when he wrote in his book about them? We discard all such cumbersome, meaningless, or otherwise objectionable phrases as names of muscles, and select or invent other words that we conceive to be preferable. We are sustained in this raid on the time-honored bugbears by the conviction that the horror with which conservative age views new names for old things is less than the terror with which progressive youth gazes upon our cherished fetiches, and is no greater than our own irreverence for the sleepy old gods of the amphitheatre.

But the world moves, and ideas move it, just as nerves move muscles. Half the difficulty of anatomy is inherent; the other half is in wordiness. The trouble with the student is more in the names of things than in the things themselves. He mistakes one for the other, his head swims, and then he founders in a Latin storm at sea. But that need not be.

Gray's "Anatomy" takes about 450 words to name the muscles which we here name in 303 words. Gray's names run from one word to five words apiece, averaging more than two. Our names are mostly in one word; a few are in two words; none in three or more. This is a positive practical advantage.

The old names show scarcely a trace of any system of naming. Some muscles are named from their size or shape or other appearance; some from their relative position; some from their origin or insertion; some from their function or office. Some names are historical or complimentary; others fanciful or whimsical. Some are words, others are phrases; some are nouns, others adjectives or participles; some are singular, others plural;

some are Greek or Latin, others English or dog-Latin or nondescript. The old classification or arrangement of the muscles in groups for the purposes of description is scarcely less artificial and faulty. Muscles have been mostly divided into "regions," "layers," etc., by a trick caught at the dissecting-table. This presumes upon the ability of the man on the table to describe his own muscles scientifically, whereas he can only furnish the information which may enable another to construct a scientific system of myology.

We have gone by the old-fashioned landmarks as far as possible, but never hesitated to leave them behind if we must, in threading our way through the muscular labyrinth by the Ariadnean clew which the nervous system affords. For a favorable sample of the way our plan works, take the muscles of the thigh. It was only necessary to see in the so-called "obturator externus" a muscle of the adductor set, and in the so-called "tensor vaginæ femoris" a muscle of the glutæal region, to see all the femoral muscles leap into their proper places at the will of the lumbar and sacral plexuses. Then we have several clean-cut nervimuscular groups: these we call *antecrural*, *adductorial*, *glutæal*, *coxal*, and *postfemoral*. The first two of these are innervated from the *lumbiplex;* the last three from the *sacriplex*. The first is anterior, and presided over by the antecrural nerves. The second is internal, governed by the obturator nerves. The third is posterior, superior, and superficial, ruled by two special branches of the sacriplex. The fourth is posterior, superior, and deep-seated, impressed directly by as many sacriplexal nerves as there are muscles. The fifth is posterior, innervated by branches of the *magnisciatic* nerve. Next, how shall these muscles be *named* so as to show to which of these five sets every one of them belongs? The easiest way is to make the names in each set agree with one another in termination, and differ from those of all the other sets. Acting on this plan, and also compromising with the old lack of system, we name the muscles thus:

Antecrural Group: *Sarticruræus*, *recticruræus*, *extracruræus*, *medicruræus*, *intracruræus*, *subcruræus*.

Adductorial Group: *Obturiductor*, *pectiniductor*, *breviductor*, *longiductor*, *magniductor*, *graciliductor*.

Glutæal Group: *Vaginiglutæus*, *ectoglutæus*, *mesoglutæus*, *entoglutæus*.

Coxal Group: *Pyriformis*, *obturiformis*, *quadratiformis*, *gemelliformis*, *geminiformis*.

Postfemoral Group: *Tendinosus*, *membranosus*, *bicipitosus*.

Here are twenty-four words for twenty-four muscles. Gray has forty for the same. Notwithstanding that this changes almost every name in the text-book, we imagine there are few students who will not recognize them all on sight.

Such systematic classification and methodical nomenclature we have carried out to the best of our ability in the present paper, hoping that we have at any rate got rid of a good deal of dead wood, if we have not also improved the order of things in other respects. All the names we use are printed in **thick type**, and the old ones are bracketed in quotation-marks opposite them for facility of comparison. Our names are all nouns, in due Latin *form*, nominative case, masculine gender, and mostly singular number. A very few of them are bad Latin, like *malledius*, *complicalis*, and *trachelalis*, but they look well enough, and we found reason for inventing them. We sometimes compound words of Greek origin with Latin prepositions, or vice versa, and sometimes clip a good deal in compounding; but, as a rule, the words are kept pure in fact as in form. We also incidentally introduce some new names of nerves, like *sacriplex* for "sacral plexus," having in view the revision of the nerves in like manner on some future occasion.

We begin by advancing the following:

General Propositions.

I. Agreeably to the plan of the vertebrate skeleton, which consists of a main axis or trunk, with diverging appendages or limbs, the muscular system is divisible into Axial and Appendicular musculation.

Axial muscles are those which belong to the axial skeleton—that is to say, to the trunk, including the head. The muscles of the head, neck, chest, belly, back, and perinæum, are *axial*.

Appendicular muscles are those which belong to the appendicular skeleton—that is to say, to the limbs. The muscles of the anterior and posterior extremities are *appendicular*.

II. Spinal nerves first divide into "anterior" and "posterior" trunks. These prime *divisions* are respectively Hypaxial and Epaxial.

Hypaxial nerves are those which pass below the vertebral axis—that is, in man, in front of the bodies of the vertebræ.

Epaxial nerves are those which pass above the vertebral axis—that is, in man, behind the bodies of the vertebræ.

Cranial nerves do not divide like spinal nerves. Those of them which are motor — that is, those which innervate muscles—correspond to "anterior" divisions only of spinal nerves. They are therefore *hypaxial*.

It is only the "anterior" or *hypaxial* divisions of spinal nerves which form the great knots known as the *cervical*, *brachial*, *lumbar*, and *sacral plexuses*. The "posterior" or *epaxial* divisions are smaller, as a rule, and scarcely or not plexused; their motor function is confined almost entirely to the "muscles of the back," and they have nothing to do with the appendicular muscles.

III. The muscles of the limbs are innervated entirely from *hypaxial* nerves—that is to say, from the several plexuses, together with the accessispinal nerve, which is the equivalent of a hypaxial nerve, and only a cranial nerve "by courtesy." Muscles of the limbs are therefore *hypaxial* as well as *appendicular*.

IV. All the prevertebral muscles—that is, those which are situated in front of the spinal column—are innervated from anterior divisions of spinal nerves, and are therefore *hypaxial*.

V. All the muscles of the head which are innervated by cranial nerves are innervated as above said—by equivalents of anterior divisions of spinal nerves, and therefore are also *hypaxial*.

VI. It follows from the foregoing that the "muscles of the back" are the only *epaxial* muscles of the body.

VII. Every muscle[1] which is attached to the shoulder-girdle (scapula, coracoid, or clavicle), or beyond on the fore limb, is also innervated primarily, chiefly, or entirely from the *brachiplex*, or by the accessispinal nerve; and every such muscle is a *Muscle of the Anterior Extremity*.

VIII. Every muscle which is attached to the femur or beyond on the hind limb is innervated either from the *lumbiplex* or from the *sacriplex;* and every such muscle is a *Muscle of the Posterior Extremity*.

IX. The muscles of the perinæum are *hypaxial*, but they are *non-appendicular*. For, although they attach to the hip-girdle (ilium, ischium, pubis), such connection with the appendicular skeleton is incidental, like that of various muscles of the back or belly. The perinæal muscles are *axial;* they develop in relation with the urogenital and digestive systems, and represent muscles of the head at the opposite pole of the body-axis.

X. Combining the foregoing considerations respecting (a) *Axial* and *Appendicular* skeletal relations of muscles with (b) *Epaxial* and *Hypaxial* neural relations of muscles, we lay the foundation of a rational classification of muscles as follows:

[1] Save one—the omohyoideus.

A. EPAXIAL AXIAL MUSCLES.

I. The Muscles of the Back: Dorsal Muscles.

B. HYPAXIAL AXIAL MUSCLES.

II. The Muscles of the Head: Cranial Muscles.
III. The Muscles of the Neck: Cervical Muscles.
IV. The Muscles of the Chest: Thoracic Muscles.
V. The Muscles of the Belly: Abdominal Muscles.
VI. The Muscles of the Perinæum: Perinæal Muscles.
VII. The Muscles of the Tail: Coccygeal Muscles.

C. HYPAXIAL APPENDICULAR MUSCLES.

VIII. The Muscles of the Anterior Extremity: Arm Muscles.
IX. The Muscles of the Posterior Extremity: Leg Muscles.

A. EPAXIAL AXIAL MUSCLES.

Innervated by posterior divisions of spinal nerves.

The so-called "first layer" and "second layer" of the muscles of the back are not epaxial; are not axial; and are not innervated by posterior divisions of spinal nerves. They therefore are not muscles of the back. They are hypaxial appendicular muscles of the anterior extremity.

There is little foundation in fact for the recognition of the so-called "third layer." In so far as the innervation is concerned, the "third layer" and the "fourth layer" are one, innervated by *outer branches of posterior spinal nerves.*

The so-called "fifth layer" is more distinct, being innervated by *inner branches of posterior divisions of spinal nerves.*

Lengthwise, or axially, the muscles of the back are continuous from occiput to coccyx with such slight modifications that it is needless, if not useless, to divide them into "cervical," "dorsal," "lumbar," and "sacral" regions. These muscles require to be renamed and redescribed, as well as reclassified, in order to be intelligible. The most distinct among them, after the splenii and serrati, are those which provide for the movements of the head, and of the ribs upon the vertebræ.

The "levatores costarum," which Gray puts with the muscles of the chest, are epaxial, and therefore muscles of the back.

The most unconformable muscles of the back are the splenii and the serrati.

I. THE MUSCLES OF THE BACK.

1. SUPERFICIAL GROUP.

["Third" and "Fourth" "Layers."]

Innervated by outer branches of posterior divisions of spinal nerves.

(*a*) *Spleni-serrator Series.*

1. **Capiti-splenius.** ["Splenius capitis."]
1a. **Colli-splenius.** ["Splenius colli."]
2. **Supra-serratus.** ["Serratus posticus superior."]
3. **Infra-serratus.** ["Serratus posticus inferior."]

This peculiarly unconformable series is *oblique: i.e.*, the muscles arise from spiniprocesses and proceed obliquely to mastoid portion of skull, to transprocesses of cervical vertebræ, and to ribs. The splenii draw the head back and to either side. The serrati are antagonistic respiratory muscles.

(*b*) *Spinirector Series.*

(Sacri-lumbar region.)

1. **Sacri-lumbalis.** ["Erector spinæ."]

(Lumbi-dorsal region.)

2. **Dorsi-spinalis.** ["Spinalis dorsi."]
3. **Lumbi-dorsalis.** ["Longissimus dorsi."]
4. **Lumbi-costalis.** ["Sacro-lumbalis."]
5. **Costi-costalis.** ["Musculus accessorius ad sacro-lumbalem."]

(Dorsi-collar region.)

6. **Colli-spinalis.** ["Spinalis colli."]
7. **Dorsi-cervicalis.** ["Transversalis colli."]
8. **Costi-cervicalis.** ["Cervicalis ascendens."]

(Colli-capital region.)

9. **Biventralis.** ["Biventer cervicis."]
10. **Complicalis.** ["Complexus."]
11. **Trachelalis.** ["Trachelo-mastoideus."]
